21 **Abstract.** Information about barnacles as fossil components of hard substrate
22 communities from middle latitudes in the Southern Hemisphere is scarce. Changes in
23 these barnacle communities during episodes of extinction such as occurred during the
24 Cretaceous/Paleogene (K-Pg) boundary are almost unknown. We describe encrusting
25 and boring barnacles associated with Maastrichtian and Danian oysters, evaluate
26 taphonomic processes involved, and report changes in their frequencies over time. A
27 total of 1,174 valves belonging to nine oyster species, collected from the Jagüel and
28 Roca formations of the Neuquén Basin, were analyzed. Presence/absence of barnacles
29 or their bioerosional traces were recorded, frequencies of host incrustation and
30 bioerosion were calculated, and taphonomic and statistical analyses were performed.
31 Encrusting barnacles identified on the oyster shells were assigned to *Verruca rocana*
32 Steinmann and their traces assigned to the ichnospecies *Centrichnus concentricus*
33 Bromley and Martinell. Boring barnacles are represented by traces assigned to the
34 ichnogenus *Rogerella* De Saint-Seine. A preliminary taphonomic analysis indicated that
35 late Maastrichtian and early Danian shells showed fair-poor condition by abrasion and
36 fragmentation as taphonomic attributes, while late Danian shells exhibited mostly good-
37 fair or mixed condition for both attributes. *Verruca rocana* shows no records during late
38 Maastrichtian but high frequencies of encrusted valves after the K-Pg boundary. Boring
39 barnacles represented by the trace *Rogerella* exhibited a decline in abundance during
40 early Danian but an increase at late Danian. Both encrusting and boring barnacles
41 associated with oysters presented an increase in their frequencies during late Danian.

43 **Resumen.** CIRRIPEDIOS INCRUSTANTES Y PERFORANTES A TRAVÉS DEL
44 LÍMITE CRETÁCICO-PALEÓGENO EN PATAGONIA NORTE (ARGENTINA).

45 La información sobre cirripedios como componentes fósiles de las comunidades de
46 sustratos duros de latitudes medias en el hemisferio sur es escasa. Los cambios en estas
47 comunidades durante episodios de extinción como el que ocurrió durante el límite
48 Cretácico/Paleógeno (K-Pg), son casi desconocidos. En este trabajo describimos los
49 cirripedios incrustantes y perforantes asociados a ostras maastrichtianas y danianas,
50 evaluamos los procesos tafonómicos involucrados, y registramos los cambios en su
51 frecuencias de ocurrencia en el tiempo. Se estudiaron 1.174 valvas pertenecientes a
52 nueve especies de ostras, recolectadas de las formaciones Jagüel y Roca de la cuenca
53 Neuquina. Se registró la presencia/ausencia de los cirripedios o de sus trazas
54 bioerosivas, se calcularon las frecuencias de incrustación y bioerosión y se realizaron
55 análisis tafonómicos y estadísticos. Los cirripedios incrustantes identificados fueron
56 asignados a *Verruca rocana* Steinmann y sus trazas asignadas a la icnoespecie
57 *Centrichnus concentricus* Bromley y Martinell. Los cirripedios perforantes, están
58 representados por trazas asignadas al icnogénero *Rogerella* De Saint-Seine. Los análisis
59 tafonómicos indicaron que durante el Maastrichtiano tardío y Daniano temprano, las
60 ostras muestran una condición intermedia a pobre para la abrasión y la fragmentación,
61 mientras que las ostras del Daniano tardío exhibieron una condición buena-regular o
62 mixta para ambos atributos. *Verruca rocana* no muestra registros durante el
63 Maastrichtiano tardío pero sí presenta alta frecuencia de incrustación de valvas luego
64 del límite K-Pg. Los cirripedios perforantes presentaron una declinación en la
65 abundancia, para el Daniano temprano y un aumento en el Daniano tardío. Ambos
66 grupos presentaron un aumento en sus frecuencias durante el Daniano tardío.

68 BARNACLES (Cirripedia) are a major group of crustaceans that consists exclusively of
69 sessile organisms (Glennner and Hasgaard, 2006). They are found today in all marine
70 environments, distributed from the tropics to the poles and from intertidal zones to
71 abyssal depths (Farrapeira, 2010). The radiation of cirripeds is reflected by the variety
72 of biogenic and abiogenic substrates on which they are able to attach or bore (Pitombo,
73 2010). Also, the existence of planktonic larval dispersal in some species combined with
74 a permanent calcareous shell in adults provides an adaptive strategy to occupy and
75 persist in diverse and physiologically challenging environments (Van Syoc, 2009).
76 Cirripedia mainly consists of three well-defined superorders: Thoracica (encrusting or
77 “true” barnacles), Acrothoracica (boring barnacles) and Rhizocephala (parasitic
78 barnacles) (Glennner and Hasgaard, 2006; Pitombo, 2010). Thoracica and Acrothoracica
79 use their feathery thoracopods (cirri) to suspension feed, whereas rhizocephalans are
80 parasites of other crustaceans, especially decapods (Brusca and Brusca, 2005).
81 Although encrusting barnacles have a fossil record dating back to the Cambrian (Foster
82 and Buckeridge, 1987), verrucomorphs (*i.e.*, barnacles with assymmetric plates) have
83 the earliest known representative genera from the Cenomanian–Late Maastrichtian (*i.e.*,
84 *Proverruca* Withers, 1914) and from the Upper Santonian–Upper Campanian (*i.e.*,
85 *Eoverruca* Withers, 1935) (Buckeridge *et al.*, 2008). During the Late Cretaceous,
86 *Verruca* was restricted to Europe or Australasia, but migration via an open seaway
87 along the south Pacific West Antarctic margin of Gondwana may have also provided the
88 route for *Verruca* to reach southern South America (Buckeridge, 2011). The genus
89 *Verruca* have an stratigraphic range from Maastrichtian to recent (Buckeridge *et al.*,
90 2008).
91 Boring barnacles are known from the Upper Devonian (Rodriguez and Gutschick, 1977)
92 mainly in the form of borings or cast of borings (Newman, 1987). They are limited in

93 distribution by hard substrates found largely in carbonate sedimentary rocks and on
94 skeletons of marine invertebrates (Newman 1971; Kolbasov and Newman, 2005).
95 Fossil hard substrate assemblages preserve mostly the sessile components of the original
96 communities, particularly sclerobionts (*sensu* Taylor and Wilson, 2002), which encrust
97 or bore into the shells of living and dead organisms (Taylor and Wilson, 2003; Brett *et*
98 *al.*, 2012) or mineralized skeletons, in general. These shells are sometimes the only
99 available substrates for sclerobiotic communities in soft bottom environments. In this
100 sense, oysters as hard substrates provide a good opportunity to study changes in
101 abundance, and distribution of boring and encrusting organisms.
102 Information about barnacles as fossil components of encrusting and boring communities
103 associated with hard substrates from middle latitudes in Southern Hemisphere is scarce.
104 In addition, changes in these communities during episodes of extinction like those
105 occurred during the Cretaceous/Paleogene (K-Pg) boundary are almost unknown. The
106 main aim of this work is to describe the encrusting and boring barnacles associated with
107 Maastrichtian and Danian oysters, and to report changes in their abundances over the
108 critical K-Pg transition. Also, other sclerobionts on valves were identified to know the
109 assemblage composition and asses if there is a pattern of distribution of them in the
110 considered time intervals.

111 **GEOLOGICAL AND PALEONTOLOGICAL SETTINGS**

112 The Neuquén Basin (Fig. 1) covers approximately 120,000 km² of central-western
113 Argentina (Howell *et al.*, 2005), including part of the provinces of Mendoza,
114 Neuquén, Río Negro and La Pampa. The sedimentary infilling reaches a thickness of
115 over 6,000 m and includes marine and continental deposits spanning the Late Triassic–
116 Paleocene (Casadío and Montagna, 2015).

117 During the Late Cretaceous, marine sedimentation occurred as a result of flooding from
118 the Atlantic, which began during the Maastrichtian. The Atlantic Ocean then covered an
119 estimated surface of 507,000 km² of presently emerged Patagonia (Malumián and
120 Caramés, 1995).

121 In the northwest of the basin, the Malargüe Group records its greatest thicknesses
122 outcropping at many localities situated at the foot of the Andes (Groeber, 1947;
123 Dessanti, 1973, 1978; Legarreta *et al.*, 1989, 1993; Parras *et al.*, 1998). This group is
124 composed from base to top by the Loncoche/Allen, Jagüel, Roca and Pircala/El Carrizo
125 formations.

126 During the past two decades, significant progress in the stratigraphic, sedimentological
127 and paleontological knowledge of the Malargüe Group was made. Most of these
128 advances are related to the interest generated by the 1980s in studying the events
129 around the K-Pg boundary. In this way, the Malargüe Group contains the K-Pg
130 boundary in both marine and continental facies and is considered as a key to
131 understand the changes occurring in ecosystems of the Southern Hemisphere mid-
132 latitudes during the Maastrichtian-Danian interval (Parras and Casadío, 1999).

133 The sedimentary sequence studied in this work, consists of marine Jagüel and Roca
134 formations recognized in eight localities (Fig. 1, appendix of Supplementary Online
135 Information). These units would represent the final Atlantic transgressive- regressive
136 phase of the sea that flooded the Eastern sector of the Neuquén Basin during the Late
137 Cretaceous and the early Paleogene (del Río *et al.*, 2011). The Jagüel Formation is
138 composed of marine mudstones and claystones that represent an inner shelf (Casadío,
139 1998). The Roca Formation transitionally overlaps this unit, and represents shallow
140 marine environments deposited during a regressive phase, comprising marl rocks and
141 bioclastic limestones with abundant skeletal fragments (del Río *et al.*, 2011).

142 Among the bivalves recorded in Jagüel and Roca formations, oysters are the most
143 conspicuous constituent of their fossil assemblages. The calcitic composition of valves
144 enhanced the chance of preservation of this oyster in these deposits, and also allowed
145 the identification of the sclerobiotic communities associated with them.

146 Oyster accumulations of the K-Pg transition from the Neuquén basin were studied by
147 Casadío (1998). Taphonomic and facies data collected for this work are included in
148 table 1.

149 **[Figure 1]**

150 **MATERIAL AND METHODS**

151 Nine oyster species ranging in age from late Maastrichtian to late Danian were studied
152 (Figs. 2-4; Tab. 1) to analyze the abundance and distribution of barnacles on them under
153 a binocular microscope. A total of 1,174 valves were collected randomly from the
154 Jagüel and Roca formations at several localities in the Neuquén Basin (Fig. 1) from
155 non-lithified deposits, in some of which the K-Pg boundary can be recognized (*e.g.*,
156 Bajada del Jagüel, Cerros Bayos and Liu Malal) (Concheyro and Villa, 1996; Casadío *et al.*,
157 2005; del Río *et al.*, 2007; 2011; Brezina *et al.*, 2014). Also other sclerobionts (*e.g.*,
158 boring and encrusting organisms) associated with these oysters were observed and
159 identified.

160 The analysis was focused on encrusting and boring barnacles. The frequencies of
161 occurrences of sclerobionts (*i.e.* encrusting or boring barnacles) were calculated as the
162 number of host shells encrusted or bored of the total number of shells observed for each
163 time interval. Goodness of fit tests and exact confidence intervals for the binomial
164 distribution were performed in order to assess the distribution of barnacles on oysters
165 species from different time intervals. Then, the null hypothesis was that the distribution
166 of barnacles on oyster valves is random at a significance level $\alpha=0.05$ (Zar, 1999). This

167 methodology was followed according to the analysis performed in several previous
168 works (Mauna *et al.*, 2005; Parras and Casadío, 2006; Romero *et al.*, 2013; Brezina *et*
169 *al.*, 2014).
170 Taphonomic analysis was focused on the 1,174 valves of the nine species of oysters
171 identified to assess the accumulation history of them . Fragmentation and abrasion were
172 described as taphonomic attributes using semi-quantitative taphonomic grades (Flessa *et*
173 *al.*, 1993) and presented using ternary taphograms. Three taphonomic grades were used:
174 good (grade 0 = best preservation), fair (grade 1 = intermediate) and poor (grade 2 =
175 poorest) (Kowalewski *et al.*, 1994, 1995). Shell preservation was characterized as good
176 when <5% of a sample's surface was affected by each attribute, intermediate between 5
177 and 50%, and poor when >50% of the surface was affected. Taphonomic attribute
178 analyses were adapted from Parsons and Brett (1991) and Kowalewski *et al.* (1994;
179 1995) to have a preliminary approach of transport and hydrodynamic regimes that could
180 affect bioclasts according to Kowalewski *et al.* (1995).

184 Argentina.

185 **[Figure 2-4]**

186 **[Table 1]**

187 **RESULTS**

188 Among the sclerobionts, the identified encrusters were bivalves (including oyster
189 recruits and *Spondylus* sp.), polychaetes (serpulid tubeworms), and bryozoans (35
190 species of cyclostomes and cheilostomes). Bioerosional structures produced by boring
191 activity upon the shells were also recorded on valves as sponges (*Entobia* isp.),

192 polychaetes (*Maeandropolydora* isp. and *Caulostrepsis* isp.), bivalves
193 (*Gastrochaenolites* isp.), ctenostome bryozoans (*Pennatichnus* isp.), phoronids (*Talpina*
194 isp.), and algae and fungi. Their observed frequencies can be consulted in in
195 Supplementary Online Information.

196 The recognized barnacles on the oyster shells belong to Acrothoracica (*i.e.*, boring
197 barnacles) and Thoracica (*i.e.*, encrusting barnacles). The encrusting barnacles were
198 assigned to *Verruca rocana* Steinmann, 1921. This species has depressed and
199 asymmetrical shells (Fig. 5.1-2) comprising four plates (carina, rostrum, fixed tergum
200 and fixed scutum). Rostrum and carina are longitudinally ribbed, especially near the
201 base. The diameter of shells is between 1.5 and 3 mm.

202 Also, the presence of verrucids was inferred by the identification of traces assigned to
203 the ichnospecies *Centrichnus concentricus* Bromley and Martinell, 1991. In the
204 analyzed samples, *C. concentricus* is approximately circular, with a central depression
205 which is surrounded by a flat platform whose edges mark a groove in the surface (Fig.
206 5.1, 3). The platform margin is crenulated and corresponds to the ornament of the
207 verrucid plates.

208 The boring barnacles are represented by traces assigned to the ichnogenus *Rogerella* De
209 Saint-Seine, 1951. *Rogerella* showed holes with an elliptical contour and elongated
210 distal portion, sometimes with a slight curvature (Fig. 5.4-5), and a circular or conical
211 proximal portion (Fig. 6.6). Length of the traces ranges from 1.2 to 2.5 mm. Erosion of
212 the substrate can make them seem shallower than they actually are. The holes are
213 arranged randomly and roughly equidistant, perpendicular or oblique to the substrate.
214 The traces can be found alone or in groups (Fig. 5.4).

215 The observed frequencies of encrusting and boring barnacles on oyster species are
216 shown in Table 2.

217 **[Figure 5]**

218 **[Table 2]**

219 In general, late Maastrichtian shells are typically in fair-poor condition for both
220 taphonomic attributes (Fig. 6), with *T. damboreneae* (Cerro Butaló) consisting of the
221 poorest shells represented in the fragmentation taphogram. Furthermore, early Danian
222 oysters also exhibited fair-poor preservation for both taphonomic attributes, except for a
223 sample of *G. callophyla* from the Cerros Bayos locality with a high proportion of shells
224 in poor condition as a result of abrasion. Finally, late Danian oysters vary greatly. A
225 good-fair condition for both attributes was recorded for *C. ameghinoi* from Cerros
226 Bayos, General Roca and Bajada de Jagüel, while the taphonomic condition of the other
227 samples representing *O. wikensi* and *P. (Ph.) sarmentoi* varied greatly.

228 **[Figure 6]**

229 ***Barnacles through K-Pg boundary***

230 *V. rocana* (*i.e.* encrusting barnacles) and their trace *C. concentricus* in the studied
231 localities showed absence of records during the late Maastrichtian, low frequency
232 during the early Danian, and high frequency during the late Danian (Fig. 7.1). On the
233 other hand, the records of *Rogerella* (*i.e.* boring barnacles) showed significant
234 differences in its frequency, reflecting an important decrease during early Danian,
235 although, during the late Danian its abundance increased considerably (Fig. 7.1).
236 Goodness of fit showed significant differences for both encrusting and boring barnacles
237 on valves of different ages (*i.e.* late Maastrichtian, early Danian and late Danian)
238 ($p < 0.0001$). But the analysis with exact confidence intervals showed that the significant
239 differences are for boring barnacles during early and late Danian (Fig. 7.2), considering
240 that the expected frequency (EF) is lower than the observed frequency (OF) during early
241 Danian and the OF is higher than the EF during late Danian.

242 Goodness of fit also showed significant differences in the distribution of both encrusting
243 and boring barnacles on valves of different oyster species ($p < 0.001$). The analysis with
244 exact confidence intervals showed that there are significant differences for boring
245 barnacles on *P. (Ph.) vesicularis*, *T. damboreneae*, *O. wilckensi* and *P. (Ph.) sarmientoi*.
246 For encrusting barnacles, significant differences are on *O. wilckensi* and *C. ameghinoi*
247 (Figs.7.4-6).

248 **[Figure 7]**

249 **DISCUSSION**

250 Buckeridge *et al.* (2008) considered that it is more common to find verrucids preserved
251 as disarticulated wall plates than articulated ones. In the analyzed samples most of
252 encrusting barnacles are preserved articulated. However, we recognized oysters with the
253 trace *C. concentricus* in which an eroded platform was seen. Darwin (1854) mentioned
254 this trace is produced by recent specimens of *Verruca stroemia* (Müller, 1776) and
255 found them to be comparable to fossil material. In addition, Santos *et al.* (2005)
256 described similar traces and assigned them to *Anellusichnus* Santos, Mayoral, and
257 Muñiz, 2005, although this ichnogenus is produced by balanomorphs and can have more
258 crenulated edges in later stages. This feature was not observed in the studied specimens.
259 The recorded trace openings have the form of a slot, and the hole is narrower towards
260 the bottom. Recent acrothoracican barnacles which belong to Lithoglyptidae Aurivillius,
261 1892, leave this trace. They penetrate the substrate during the larval stage (*Cypris*
262 larvae), probably by chemical dissolution, and when they are adults, they use chitinous
263 bristles present on the outer side of their mantle to enlarge the chamber (Abletz, 1993,
264 Kolbasov and Newman, 2005). The boring protects the animal body as they lack shell
265 plates (Abletz, 1993). According to Lambers and Boekschoten (1986), the recent
266 species *Trypetesa nasseroides* Turquier, 1967, lives in gastropods shells inhabited by

267 hermit crabs, and they bore by a combination of chemical and mechanical processes.
268 These authors considered that the mode of life and the drilling processes of these
269 organisms can be compared with fossil barnacles whose traces are assigned to
270 *Rogerella*.
271 Late Maastrichtian and early Danian oyster shells exhibited fair-poor condition for both
272 abrasion and fragmentation, while late Danian shells exhibited mostly good-fair
273 condition for the same attributes. These oyster species probably are showing differences
274 in abrasion and fragmentation as a consequence of different preservational
275 environments, such as hydrodynamic regime, bioerosion, degree of subaerial exposure,
276 differences in the size and architecture of the shells, or some combination of these
277 parameters (Kowalewski *et al.*, 1995).
278 Shells of *T. damborenae* (Cerro Butaló) are included in accumulations associated with
279 bars and tidal channels showing poor preservation, probably caused by short distances
280 of transport and reworking. Nevertheless, fragmentation can result also from a
281 combination of both physical and biological processes (Zuschin *et al.*, 2003). This is
282 coincident with the high bioerosion observed in this oyster, represented mostly by
283 sponges, boring barnacles, and phoronids.
284 *Gryphaeostrea callophyla* (Cerros Bayos) shells are included in parautochthonous
285 accumulations associated with offshore beds and probably experienced little transport.
286 In this case various factors including microboring activity, and dissolution could result
287 in the loss of surface shell material (Schneider-Storz *et al.*, 2008). Also, shells revealed
288 low frequencies of sclerobionts, with poorly preserved bryozoans on external shell
289 surfaces and low bioerosion represented mostly by polychaetes on internal surfaces.
290 Additionally, in both ternary taphograms, the late Danian oysters *Ostrea wilckensi* and
291 *Pycnodonte (Ph.) sarmientoi* presented mixed taphonomic grades following the

292 description of Kowalewski *et al.* (1995). For both oyster species, a high grade of
293 bioerosion and encrustation could indicate that there was no rapid burial or subaerial
294 exposure (Kowalewski *et al.*, 1995). Moreover, *O. wilckensi* is preserved mostly in life
295 position (*i.e.*, developing clusters or nests) and has a high frequency of articulation.
296 Sclerobionts are preferentially distributed on external shell surfaces indicating *in vivo*
297 colonization. Mixed taphonomic grades also correlate well with the inferred
298 depositional environments, where all oysters of Danian age were included in
299 accumulations associated with bars and tidal channels characterized by a fluctuating
300 hydrodynamic regime.

301 In this study, a preliminary examination of the taphonomic condition of Maastrichtian
302 and Danian oysters was performed. Considering that the increase in frequency of
303 occurrence of boring barnacles during the late Danian would be related to taphonomic
304 constraints more than evolutionary or paleoecology patterns, a larger sample would be
305 necessary for more accurate interpretations of the studied environments at the three
306 times intervals. Additionally, according to Parsons and Brett (1991), skeletal fragments
307 should be included in futures taphonomic studies as the fragments may be more
308 sensitive to taphonomic processes. They can provide useful and different information
309 than whole or broken shells.

310 ***Barnacles through K-Pg boundary***

311 There is a limited database about the changes over time in sclerobiotic communities,
312 and even less in boring and encrusting barnacles. However, Brett *et al.* (2012) suggested
313 that the records of Cretaceous to modern sclerobiotic communities apparently have not
314 changed drastically in diversity and abundance since the re-emergence of encrustation
315 in the Jurassic. These communities were dominated by the same sclerobionts as those in
316 the Jurassic (*e.g.*, encrusting foraminifers, serpulid worms, cheilostome bryozoans,

317 coralline algal encrusters, cementing bivalves as oysters, clionid borings and ctenostome
318 etchings) (Brett *et al.*, 2012). Barnacles are an ancient group that remains very
319 successful today, both in number of species and abundance (Newman and Abbott,
320 1980). However, it seems that across the K-Pg boundary, at least according to the
321 Northern Patagonian records, some of them reflected a decrease in the frequency of
322 occurrence in the fossil record.

323 In this sense, and focusing on K-Pg events, The first records of *Verruca* are from the
324 Santonian of Western Australia, but it reached a wide geographic distribution during the
325 late Campanian-Maastrichtian, being recorded in Europe, Western Australia
326 (Buckeridge, 1983; Buckeridge *et al.* 2008) and South America. On the other hand, the
327 earliest verrucid barnacles recorded after the K-Pg boundary were *V. punica*
328 Buckeridge, Jagt, and Speijer, 2008, from the early Danian of Tunisia, and *V. rocana*
329 from the early Danian of Argentina. Is possible to consider that during early Danian,
330 ecological factors could have affected populations of this specie being underrepresented
331 ~~and no registered~~ in the fossil record. These factors include the **availability of resources**
332 and also **interactions between species** (Paine 1969, 1984, 1994). Also taphonomic
333 conditions could disfavor the preservation of encrusting barnacles. Verrucid barnacles
334 are commonly found preserved as isolated, disarticulated wall plates and rarely as
335 complete fossils (Buckeridge and Finger, 2001). The valves of Maastrichtian oysters
336 with poor preservation conditions tend to have not a good record of encrusting
337 barnacles, since the complete preservation of their plates is exceptional. Anyway, as
338 their traces are not recorded, this might suggest that either the taxon was not abundant,
339 it was a rare specie or it was not present at these time. Additionally, as there are
340 ~~registered~~ superficial traces made by algae and fungi (Supplementary Online
341 Information) and there are not barnacles traces, then they ~~possibly were~~ absent.

342 Taphonomic feedback (*i.e.* biotic changes driven by live/dead interactions *sensu*
343 Kidwell and Jablonsky (1983)) can be considered. Some marine invertebrates do not
344 settle or look for refuge in clumps of dead oysters, probably because pore waters
345 underneath the oysters are anoxic (Kidwell 1986). Moreover, early colonists could
346 inhibit later colonists by biochemical or other biotic interactions (Kidwell and
347 Jablonsky, 1983). Barnacles respond to stimulatory and inhibitory external signals
348 during the settling stage of their life cycle (Holmström *et al.*, 1992).

349 Possible negative effects on barnacles caused by the crisis during K-Pg also must be
350 taken into account. Buckeridge *et al.* (2008), considered the genus *Verruca* seems to
351 have persisted across the boundary and have not been drastically affected, as was the
352 case with other taxa (Macleod *et al.*, 1997; Jablonski 1998; Håkansson and Thomsen,
353 1999; Stilwell, 2003; Parma and Casadío, 2005). But the possibility of being new to the
354 region after the K-Pg boundary could also explain the low frequencies during early
355 Danian.

356 Borings made by acrothoracican cirripeds have a high richness and extensive ~~geologic~~
357 record (Seilacher, 1969). In this work, results suggest that at the K-Pg boundary
358 encrusting and boring barnacles varied their frequencies in view of the fact that the
359 preliminary analysis with exact confidence intervals showed that the OF was lower than
360 the EF during the early Danian and then, the OF was higher than the EF during late
361 Danian (Figs. 7.2-3)..

362 The preferential distribution of encrusting and boring barnacles on the species could be
363 related to many biotic and abiotic factors. For example, life habits of this oysters such as
364 clusters composed of mutually attached specimens or reclining mode of life (Stenzel
365 1971; Machalski, 1998), morphology and textures of the valves (Romero *et al.*, 2013
366 and references therein) or environmental conditions that favor the settlement of

367 barnacles larvae on the valves (Fraschetti *et al.*, 2003; Hadfield, 2011). Encrusting
368 barnacles showed preferential distribution on two late Danian oysters (*i.e.* *C. ameghinoi*
369 and *O. wilckensi*). Although their mode of life and morphology of shells are not the
370 same, the facies analysis indicates the same subtidal environment. On the other hand,
371 boring barnacles showed preferential distribution on Maastrichtian species (*i.e.* *P. (Ph.)*
372 *vesicularis* and *T. damborenae*) and late Danian species (*i.e.* *O. wilckensi* and *P. (Ph.)*
373 *sarmientoi*). With exception of *O. wilckensi*, these species have solitary mode of life,
374 different morphology of shells, but the facies association indicates same inner to
375 middle-shelf or subtidal environments. However, there is no a clear pattern that explain
376 this differential distribution.

377 Barnacles are suspension feeders and their abundance could have been reasonably
378 affected by the reduction of food supply. This hypothesis is supported by other studies
379 that postulate that the collapse of primary production across the K-Pg boundary
380 correlates with the high extinction rates in organisms dependent on primary producers
381 (Zachos *et al.*, 1989; Veron, 2008; Jiang *et al.*, 2010; Van De Schootbrugge and
382 Gollner, 2013). Conversely, Sogot *et al.* (2013) questioned the extent to which this kill
383 mechanism affected suspension feeders during the K-Pg mass extinction. If the collapse
384 of primary producers hypothesis is consider valid, the scarce record of encrusting
385 barnacles during de late Maastrichtian and early Danian could show that these
386 organisms were underrepresented and that the crisis during the K-Pg interval severely
387 affected them. This situation seemed to have changed during the late Danian, as a
388 significant increase of both encrusting and boring barnacles is recorded in the analyzed
389 samples. This increase after the earliest Danian is observed in other sclerobionts
390 associated with the same oysters (*e.g.*, encrusting bryozoans, polychaetes and bivalves)
391 (Brezina, 2013), and can also be correlated with an increase in the number of species of

392 corals, mollusks, echinoids, and crabs from low latitudes, reflecting higher seawater
393 temperatures spreading southwards (Casadío *et al.*, 2005; Aguirre-Urreta *et al.*, 2008).
394 According to Erwin (2001), evolutionary opportunities open up during mass extinction
395 have disproportionate effects on species. He stated that mass extinctions appear to cause
396 a collapse of ecospace, which will be rebuilt during recovery times, but responses in
397 organisms are variable, even between species and regions. So the ecosystem dynamics
398 during post-extinction time could be complex. Some benthic communities at other
399 localities experienced considerable diversity reduction at the K-Pg boundary, showed a
400 recovery of the early Danian community, but initially retarded, and diversified quickly
401 during the late Danian (Håkansson and Thomsem, 1999). These results are coincident
402 with bryozoan species from northern Patagonia, which are highly diverse during the late
403 Danian (Brezina *et al.*, 2011).

404 **CONCLUSIONS**

405 During early Danian *Verruca rocana*, could have been affected by ecological and
406 environmental factors, ~~being underrepresented and no registered~~, but during the late
407 Danian its frequency of incrustation increased significantly.

408 Boring barnacles represented by the trace fossil *Rogerella* exhibited a decline in their
409 frequencies at the K-Pg boundary, and during the late Danian, their abundance also
410 increased considerably.

411 In an attempt to preliminarily know the taphonomic history of the shell accumulations,
412 a differential preservation was observed. Late Maastrichtian and early Danian
413 assemblages exhibited a fair-poor condition for abrasion and fragmentation, as a result
414 of reworking and short distance transport in offshore beds. On the other hand, late
415 Danian assemblages exhibited mostly good-fair condition or a mixture for both
416 attributes, reflecting rapid burial or subaerial exposure, or a hydrodynamic regime

417 fluctuation in the depositional environment (*e.g.*, bars and tidal channels). Frequencies
418 of barnacles are higher during late Danian and these results could be correlated.
419 However it would be necessary to focus a taphonomic analysis on the barnacles for
420 more accurate interpretations.
421 Differences in distribution of encrusting and boring barnacles among the species of
422 oysters also are recorded, although there is not a clear pattern that could explain this
423 results.
424 An ecological explanation also can be considered. As it is observed in recent
425 communities, biotic and abiotic conditions regulate the dynamics of populations. The
426 hypothesis considering a collapse of primary production could explain why suspension
427 feeders were affected during the K-Pg mass extinction. In this sense, the reduction of
428 barnacles recorded in this study could reflect the decrease of food supply in the seas.
429 Although many factors could have ~~been~~ affected the boring and encrusting pattern of
430 sclerobiotic organisms, a change in barnacle abundance through the K-Pg boundary is
431 documented. In northern Patagonia, encrusting and boring barnacles associated with
432 oysters presented an increase in their frequencies during late Danian which is coincident
433 with the increase in abundance and diversity of other benthic communities of the
434 southern hemisphere.

435 **ACKNOWLEDGEMENTS**

436 This research was supported by a doctoral fellowship of the Consejo Nacional de
437 Investigaciones Científicas y Técnicas (CONICET) to S.S. Brezina. We also thank N.
438 Carmona, R. Feldmann and **anonymous reviewers** for constructive comments and
439 suggestions, which improved the final version of this paper.

734 for abrasion and fragmentation. Some species are represented in more than one locality.

735 **Figure 7. 1,** Frequencies of occurrence of oyster shells from different ages encrusted or
736 bored by barnacles. **2,** Differential distribution of barnacles through time. Note that
737 there is a significant difference between expected frequency (EF) and observed
738 frequency (OF) of barnacles during the late Danian. **3-6,** Differential distribution of
739 barnacles on oyster species. Note that significant differences between expected
740 frequencies (EF) and observed frequencies (OF) of barnacles are indicated by (*). Error
741 bars represent confidence intervals.

TABLE 1. *Species of oysters studied and relevant information*

<i>Species of oysters</i>	<i>Fossil locality</i>	<i>Unit</i>	<i>Age</i>	<i>Taphonomic data of oyster accumulations</i>	<i>Facies data</i>
<i>Amphidonte mendozana</i> (Ihering, 1907)	Huantraico (Neuquén)	Roca Fm.	late Maastrichtian	Valves grouped in nests or in parautochthonous accumulations. Dense packing, good size-selection, convex-up valves, poor disarticulation and moderate fragmentation.	Valves are included in mudstones. Facies association indicates inner to middle-shelf environments.
<i>Pycnodonte (Phygraea) vesicularis</i> (Lamarck, 1806)	Bajada del Jagüel (Neuquén)	Jagüel Fm.	late Maastrichtian	Valves grouped in parautochthonous accumulations or in life position. Dispersed packing, poor size-selection, convex-up valves and moderate disarticulation and fragmentation.	Valves are included in mudstones. Facies association indicates inner to middle-shelf environments.
<i>Turkostrea damborenae</i> Griffin, Casadio and Parras, 2005	Cerro Butaló (Mendoza) Ranquil Có (Mendoza)	Roca Fm.	late Maastrichtian	Valves grouped in parautochthonous accumulations. Dispersed packing, good size-selection, chaotic orientation, good disarticulation and por fragmentation.	Valves are included in mudstones. Facies association indicates inner to middle-shelf environments (Jagüel Formation) or shallow subtidal environments (Roca Formation).
<i>Pycnodonte (Phygraea) burckhardti</i> (Böhm, 1903)	Cerros Bayos (La Pampa); General Roca (Río Negro)	Roca Fm. Jagüel Fm.	early Danian	Valves grouped in parautochthonous accumulations or in life position. Dispersed packing, poor size-selection, convex-up valve, poor disarticulation and moderate fragmentation.	Valves are included in mudstones. Facies association indicates inner to middle-shelf environments.
<i>Gryphaeostrea callophylla</i> (Ihering, 1903)	Cerros Bayos (La Pampa); General Roca (Río Negro)	Roca Fm. Jagüel Fm.	early Danian	Valves grouped in parautochthonous accumulations. Dispersed packing, poor size-selection, convex-up valves, poor disarticulation and moderate fragmentation.	Valves are included in mudstones. Facies association indicates inner to middle-shelf environments.
<i>Turkostrea argentina</i> Griffin, Casadio and	Liu Malal (Mendoza)	Roca Fm.	early Danian	Valves grouped in parautochthonous accumulations. Dispersed packing, good	Valves are included in mudstones. Facies association indicates shallow

Parras, 2005

<i>Cubitostrea ameghinoi</i> (Ihering, 1902)	<i>Cerros Bayos (La Pampa); General Roca (Río Negro); Bajada del Jagüel (Neuquén)</i>	<i>Roca Fm.</i>	<i>late Danian</i>	size-selection, chaotic orientation, good disarticulation and poor fragmentation. Valves grouped in parautochthonous accumulations. Dense packing, good size-selection, chaotic orientation, Good disarticulation and moderate fragmentation.	subtidal environments. Valves included in massive wackstones. Facies association indicates shallow subtidal environments.
<i>Ostrea wilckensi</i> Ihering 1907	<i>Gral. Roca (Río Negro)</i>	<i>Roca Fm.</i>	<i>late Danian</i>	Valves, grouped in nests or in parautochthonous accumulations. Dense packing, poor size-selection, associated in nests, poor disarticulation and fragmentation.	Valves included in massive grainstones. Facies association indicates shallow subtidal environments.
<i>Pycnodonte (Phygraea) sarmientoi</i> Casadío, 1998	<i>Casa de Piedra (La Pampa)</i>	<i>Roca Fm.</i>	<i>late Danian</i>	Valves grouped in parautochthonous or allochthonous accumulations. Dense packing, poor size-selection, chaotic orientation, good disarticulation and fragmentation.	Valves included in massive packstones. Facies association indicates shallow subtidal environments.

TABLE 2. Observed frequencies of barnacles on oyster valves according to the species, biozones (Papú et al., 1999) and ages.

Species of oysters	Biozones	Age	Number of valves (n)	Encrusting barnacles	Boring barnacles
<i>P. (Ph.) vesicularis</i>	CC25	late Maastrichtian	89	0	2
<i>T. damboreneae</i>	CC26	late Maastrichtian	137	0	29
<i>A. mendozana</i>	CC25-CC26	late Maastrichtian	82	0	0
<i>G. callophylla</i>	NP1	early Danian	178	0	0
<i>P. (Ph.) burckhardti</i>	NP1	early Danian	179	1	0
<i>T. argentina</i>	NP1-NP2	early Danian	82	0	1
<i>O. wilckensi</i>	NP1-NP4	late Danian	84	45	1
<i>P. (Ph.) sarmientoi</i>	NP4	late Danian	94	31	21
<i>C. ameghinoi</i>	NP4	late Danian	249	19	34
Total			1.174	96	88
