Title: Phosphorylated 11S globulins in sunflower seeds

Editor's decision: Minor Revision

Dear Dr. Derek Bewley,

We appreciate the reconsideration of the MS entitled ***Phosphorylated 11S globulins in sunflower seeds,*** by Quiroga *et al.*

Reviewers requested a few minor revisions that have been taken into account and modified in the present version. We hope that the changes introduced will fully meet the requirements of SSR.

Kind regards,

Mariana Regente

Response to the Reviewers

Comments to Author:

Thank you for making the changes as requested. There are still a few minor revisions that need to be made, particularly in the Tables and Figure legends, but then the paper is acceptable.

Answer: All the suggestions of the reviewer have been taken into account and modified in the revised MS.

Phosphorylated 11S globulins in sunflower seeds

Running head title: Phosphorylation of sunflower storage proteins.

Abstract

Phosphorylation of sunflower storage proteins.

Helianthinins are storage proteins present in *Helianthus annuus* seeds belonging to the 11S globulin family. We describe here that a fraction of the helianthinins is phosphorylated. This conclusion is supported by different criteria including identification by MALDI-TOF of major protein bands revealed with a specific dye for phosphoproteins, anti-phosphoserine antibody and binding to a phosphoprotein affinity matrix. Moreover, we show that the phosphorylation status of helianthinins changes following germination.

Introduction

Seed storage proteins accumulate in high amounts during the late stages of seed development and provide nitrogen for seed germination and early seedling growth. These proteins have been classified into albumins, globulins and glutelins based on their solubility in water, saline, and NaOH solutions respectively (Osborne, 1924). Helianthinin, the main storage protein of sunflower seeds, belongs to the salt soluble 11S globulin fraction (Raymond *et al*., 1995). These globulins are composed by α and β subunits assembled as a hexamer (Shewry *et al.*, 1995). They are synthesized as a precursor in the rough endoplasmic reticulum and follow the secretory pathway to be delivered into storage vacuoles. Sequence analysis revealed that the gene encoding the sunflower 11 S precursor (Helianthinin G3) contains a signal peptide responsible for its targeting to the secretory pathway, followed by the coding sequence for α and β chains (Vonder Haar *et al.*, 1988). In fact, the proglobulin containing the α and β polypeptides is proteolytically cleaved after disulfide bond formation and transported through the secretory system as intermediate trimers that further assemble into the mature hexameric form (Shewry *et al*., 1995). On the other hand, helianthinins are polymorphic and their subunit composition varies among different sunflower cultivars. At least six types of subunits with molecular masses ranging from 40 to 64 kDa have been described so far, consisting in different combinations of the large (32-40 kDa) acidic α polypeptide and the small (20-25 kDa) basic β polypeptide (Rahma and Narasinga, 1979; Schwenke *et al.*, 1979).

Reversible protein phosphorylation is one of the most frequent post-translational modifications and its relevance is that it regulates diverse cellular processes. Protein phosphorylation in eukaryotes mostly occurs by the addition of a phosphate group on certain serine and threonine residues, whereas phosphorylation on tyrosine residues is less abundant. Post-translational modifications of a protein can determine its activity state, localization, turnover, and interactions with other proteins (Zolnierowics and Bollen, 2000). Besides its well-known role in several signaling pathways activating and deactivating enzymes, phosphorylation participates in an expanding catalogue of physiological functions in plants (Kline-Jonakin *et al.*, 2011). Among them, it plays a key role during embryogenesis and seed germination (Fujii and Zhu, 2009; Nakashima *et al.*, 2009). Also, Wan *et al.* (2007) have shown that the 12S globulin cruciferin is the major phosphorylated protein in *Arabidopsis thaliana* seeds. A total of 20 phosphorylation sites were identified on this globulin, including serine, threonine and tyrosine residues (Wan *et al.*, 2007).

Although a specific function was not assigned to this post-translational modification, cruciferin processing and mobilization were suggested. In this respect, Ghelis *et al*. (2008) detected changes in cruciferin tyrosine-phosphorylation in response to ABA treatment, suggesting this is induced by ABA to prevent cruciferin proteolysis. Agrawal and Thelen (2006) identified in a proteomic study of *B. napus* phosphoproteins belonging to 10 major functional categories, including storage proteins during seed filling. A recent analysis of seed maturation in *Arabidopsis*, rapeseed, and soybean detected novel orthologs of seed storage proteins using a phosphoproteomic approach (Meyer *et al*., 2012).

Taking into account these observations, the aim of this work was to elucidate whether phosphorylated storage proteins are present in sunflower, a phylogenetically distant species**.**

Materials and Methods

Protein sample preparation and analysis

Helianthus annuus L. seeds (line 10347 Advanta Semillas SAIC) were sterilized in 27.5 mg/ml sodium hypochlorite for 30 min, rinsed with sterile water and subjected to imbibition for the indicated times at 25º C. Petri dishes containing wet Whatman filter paper under sterile conditions were used. Dried seeds, germinating seeds (16 and 24 h of imbibition) and seedlings (48, 90 and 96 h of imbibition) were subjected to pulverization and extracted in the following buffer: 50 mM Tris-HCl pH 7.5, 2 mM DTT, 0.1 M EDTA, protease and phosphatase inhibitors (Martin *et al*., 2007).

Protein concentration was determined by the bicinchoninic acid method (Smith *et al*., 1985) using bovine serum albumin as standard. Protein fractions (50 μg) were resolved in 12 % SDS-PAGE (Laemmli, 1970) and stained with Coomassie Brilliant Blue R-250 or Colloidal Coomassie Blue (Neuhoff *et al.*, 1988). Western blot assays were carried out by protein transfer onto nitrocellulose membranes. Rabbit anti-phosphoserine 1:500 (Invitrogen) or sunflower anti-11S globulin antibodies provided by Dr. S. Petruccelli (1:1000) were used as primary antibodies and an anti-rabbit IgG coupled to alkaline phosphatase (Sigma) was used as secondary antibody (1:10000).

2D-PAGE

Homogenates from imbibed seeds (100 μg protein) were subjected to chloroform-methanol precipitation and the pellet was suspended in 7 M urea, 2 M thiourea, 4 % (w/v) CHAPS, 100 mM DTT, 0.2 % (v/v) ampholytes pH 3-10 (BioRad), trace of bromophenol blue. Samples were loaded onto pH 3–10 nonlinear**,** immobilized pH gradient strips (7 cm, ReadyStrips, BioRad). Isoelectric focusing was performed applying the following conditions: for the rehydration step the voltage was maintained for 16 h at 50 V, and then the proteins were focused at 9000 V/h at 20ºC. After isoelectric focusing the strips were equilibrated in 375 mM Tris-HCl pH 8.8, 6 M urea, 20 % (v/v) glycerol, 2 % (w/v) SDS, 2 % (w/v) DTT, followed by 375 mM Tris-HCl pH 8.8, 6 M urea, 20 % (v/v) glycerol, 2 % (w/v) SDS, 2.5 % (w/v) iodoacetamide. Second dimension was carried out according to Laemmli (1970) in 12 % gels at 150 V and PeppermintStick phosphoprotein molecular mass standards (Invitrogen) were loaded in the first gel lane. After SDS-PAGE, gels were fixed with 50 % (v/v) methanol and 10 % (v/v) acetic acid for 30 min, washed with distilled water, stained with Pro Q Diamond phosphoprotein stain (Life Technologies) according to the

manufacturer's instructions and scanned with a FluorImager instrument (Amersham Biosciences) using 514 nm laser as excitation source and a 570 nm band-pass emission filter. After, gels were stained with SYPRO Ruby (Life Technologies) and scanned using a 488 laser as excitation source and a 610 band-pass emission filter.

MALDI-TOF

Protein bands and spots indicated in the text were automatically excised from 1D and 2D gels employing Investigator ProPic robotic workstation (Genomic Solutions, UK). Gel pieces were digested with trypsin according to standard protocols in a ProGest station (Genomic Solutions). MS analyses of peptides were performed in a 4700 Proteomics Station (Applied Biosystems, USA) as previously described (Pérez-Reinado *et al*., 2007). Protein identification was assigned by comparing the obtained peptide mass fingerprinting with the non-redundant plant database, using a Mascot 1.9 search engine (Matrixscience, UK) (Pinedo *et al*., 2012).

Phosphoprotein purification

Phosphoprotein enrichment was performed employing phosphoprotein affinity columns (Qiagen) according to the manufacturer´s instructions and the previously described modifications adapted for plant extracts (Meimoun *et al.*, 2007). Seeds were decorticated and protein was extracted using 25 mM MES, 1 M NaCl, 0.25 % (w/v) CHAPS, protease inhibitors and Benzonase Nuclease stock solution (Phosphoprotein Purification Kit, Qiagen). Protein extracts (5 mg) were loaded onto a Qiagen column and after washing with loading buffer (8 ml) bound phosphoproteins were eluted with 3 ml of elution buffer (Qiagen) and submitted to MALDI TOF for identification.

Results and Discussion

As a first approach to detect putative phosphorylated proteins in sunflower seeds we performed 2D SDS-PAGE of 16-h-imbibed seed protein extracts and the resulting gels were sequentially stained for phosphoprotein detection (Pro-Q Diamond stain) and total protein (Sypro Ruby). Pro-Q Diamond phosphoprotein stain allows in-gel detection of phosphate groups attached to tyrosine, serine or threonine residues (Oh *et al.*, 2009; Chitteti and Peng, 2007; Laugesen *et al.*, 2006). Fig. 1B shows that a limited number of spots were clearly detected upon Pro-Q Diamond staining. Among them, three spots that were consistently reproducible and could be major seed proteins were further analyzed by peptide mass fingerprinting to identify them. They were digested with trypsin, submitted to MALDI-TOF and putatively identified using Mascot software on the Genbank database. Table 1 summarizes the data obtained. The three spots matched to the 11S globulin seed storage protein G3 (Helianthinin G3) from *Helianthus annuus* (Uniprot ID P19084). Also, good agreement was observed between the experimentally-determined molecular mass of those spots and that predicted for β subunit of Helianthinin G3 (20.98 kDa). Helianthinin G3 corresponds to the precursor protein of 493 amino acids which, as described for other 11S globulins, is further cleaved into two chains: the acidic chain (α subunit), and the basic chain (β subunit) (Rahma and Narasinga, 1979; Schwenke *et al*., 1979; Vonder Haar *et al.*, 1988; Shewry *et al.*, 1995). Indeed, according to proteomic criteria all the three spots detected with the phosphoprotein specific stain can be assigned as 11S globulins. The phosphorylated spots between 35-40 kDa correlate with major spots in Fig 1A (total proteins). One major spot (~35 kDa and acid isoelectric point) was clearly visible under Pro-Q Diamond staining, whose molecular mass and isoelectric point are consistent with the α subunit. Even though these spots could not be identified by peptide mass fingerprinting, their features suggest that they correspond to α subunits of 11S globulins.

Supporting the suggestion that 11S globulin subunits are phosphorylated *in vivo,* a bioinformatic tool (NetPhos program, http://www.cbs.dtu.dk/services/NetPhos/) (Blom *et al.*, 1999) predicts 16 putative phosphorylation sites on the Helianthinin G3 precursor sequence. These correspond to 14 serines, 1 threonine and 1 tyrosine (Fig. 2), covering both α and β subunits. To experimentally confirm this presumption we used a strategy based on the purification of phosphoproteins by affinity chromatography; the robustness of this procedure has been reported (Laugesen *et al.*, 2006 Meimoun *et al*., 2007). Total seed extracts were loaded onto a Qiagen affinity matrix and eluted

proteins were fractionated by SDS-PAGE followed by MALDI-TOF analysis of the major proteins. Among them, four bands could be identified and all matched to the 11S globulin precursor G3 (Table 2). Thus several criteria indicate that 11S globulins from imbibed sunflower seeds are phosphorylated: they are detected by a phosphoprotein specific stain, they are retained in a specific affinity matrix and, in both cases, their identity can be confirmed by peptide mass fingerprinting.

In *Arabidopsis* the phosphorylation of cruciferins involves key residues allowing protein assembly, processing and mobilization (Wan *et al*., 2007), and changes in phosphorylation are regulated by ABA treatment (Ghelis *et al.*, 2008). In this context, it can be hypothesized that globulins can vary in their phosphorylation status according to their physiological state. Thus, we have investigated whether phosphorylation of helianthinins can be regulated during seed germination and seedling growth. We have compared the total seed protein profile (Fig. 3A) and that of phosphoproteins detected with an anti-P-Ser antibody (Fig. 3B). As observed in Fig 3A, the expected protein pattern was observed in dry seeds (Raymond *et al.*, 1995; Molina *et al.*, 2004; Serre *et al*., 2001) with major bands of around 32-40 and 20-25 kDa corresponding to 11S globulin α and β subunits, respectively. In addition, there were bands of around 60 kDa that could correspond to an αβ subunit (Molina *et al*., 2004). The identity of these bands was also confirmed by immunoblotting because they were recognized by sunflower anti-11S globulins serum (not shown). The protein pattern in dry seeds does not change during the first 24 h of imbibition, but modification in the protein profile occurs thereafter (Fig. 3 A). Particularly, bands around 40 kDa (α subunit) consistently decrease due to their mobilization, as previously reported (Shewry *et al.*, 1995). The 11S subunits appear to be differently phosphorylated during seedling growth while the band of around 60 kDa retains the same phosphorylation status (Fig. 3B). Even if bands of ~22 kDa (β subunit) are barely detected by the anti-P-Ser antibodies, subunits around 40-kDa are clearly visible from 16 to 48 h of seed imbibition while they are almost undetectable in dried seeds and after 90-96 h. The absence of phosphorylated α subunits after 2 days could be attributed to their degradation, since they are also undetectable by Coomassie Blue staining (Fig 3A). Dry seeds show a typical pattern of helianthinins but are barely detected by anti-P-Ser.

In conclusion, the phosphorylation of helianthinins appears to be induced following the completion of germination. Even though the basis and role of this post-translational modification is unknown, our results are indicative of the necessity for future investigations to analyze the

relationship between storage protein phosphorylation and mobilization during post-germinative growth.

Acknowledgements

The authors thank Dr. Silvana Petruccelli for providing the sunflower anti-11S globulins antiboby. This work was supported by the AECI (Agencia Española de Cooperación Internacional), AUIP (Asociación Universitaria Iberoamericana de Postgrado) and additional grants from CONICET and the University of Mar del Plata (Argentina).
