# Peptide model XXVIII: An exploratory ab initio and density functional study on the side-chainbackbone interaction in N -acetyl-L-cysteineN -methylamide and N -formyl-L-cysteinamide in their $\gamma_{L}$-backbone conformations 

M.A. Zamora, H.A. Baldoni, A.M. Rodriguez, R.D. Enriz, C.P. Sosa, A. Perczel, A. Kucsman, O. Farkas, E. Deretey, J.C. Vank, and I.G. Csizmadia

#### Abstract

A conformational and electronic study on the energetically preferred conformations ( $\gamma_{\mathrm{L}}$ ) of N - and Cprotected L-cysteine ( $\mathrm{P}-\mathrm{CONH}-\mathrm{CH}\left(\mathrm{CH}_{2} \mathrm{SH}\right.$ )-CONH-Q, where P and Q may be H or Me ) was carried out. After restraining the backbone ( BB ) conformation to its global minimum ( $\gamma_{\mathrm{L}}$ or $\mathrm{C}_{7}^{\mathrm{eq}}$ ), all nine possible side-chain (SC) conformations were subjected to geometry optimization at the HF/3-21G and the B3LYP/6-31G(d,p) levels of theory. Seven of the nine side-chain conformers were located on the potential-energy surface. All conformers were subjected to an AIM (atoms in molecules) analysis. This study indicates that three of the seven optimized conformers exhibited either or both SC $\rightarrow$ BB- or BB $\rightarrow$ SC-type intramolecular hydrogen bonding. Five conformers, however, had distances between a proton and a heteroatom that suggested hydrogen bonding.

Key words: L-cysteine diamides, side-chain potential-energy surface, ab initio and DFT geometry optimization, AIM analysis, intramolecular hydrogen bonding.

Résumé : On a réalisé une étude conformationnelle et électronique des conformations énergétiquement privilégiée ( $\gamma_{\mathrm{L}}$ ) de la l-cystéine N - et C-protégée ( $\mathrm{P}-\mathrm{CONH}-\mathrm{CH}\left(\mathrm{CH}_{2} \mathrm{SH}\right.$ )-CONH-Q; P et Q peuvent être égaux à H ou à Me). Ainsi, en retreignant la conformation du squelette ( BB ) à son minimum global ( $\gamma_{\mathrm{L}}$ ou $\mathrm{C}_{7}^{\mathrm{eq}}$ ), on a soumis les neuf conformations possibles pour la chaîne latérale (SC) à une optimisation de la géométrie aux niveaux HF/3-21G et B3LYP/6-31G(d,p) de la théorie. Sept des neuf conformères de la chaîne latérale se situent sur la surface d'énergie potentielle. Tous les conformères ont été soumis à une analyse par la méthode des atomes dans les molécules (AIM). Cette étude indique que trois des sept conformères optimisés présentent l'une ou l'autre ou les deux types de liaisons intramoléculaires $\mathrm{SC} \rightarrow \mathrm{BB}$ ou $\mathrm{BB} \rightarrow \mathrm{SC}$. Toutefois, dans cinq des conformères les distances entre un proton et un hétéroatome suggèrent l'existence d'une liaison hydrogène.

Mots clés : diamides de la L-cystéine, surface d'énergie potentielle de la chaîne latérale, optimisation ab initio et DFT de la géométrie, méthode des atomes dans les molécules (AIM), liaison hydrogène intramoléculaire.
[Traduit par la Rédaction]

## Introduction

Cysteine (Cys) is the sulfur analogue of serine (Ser). Both amino acid residues may conveniently be studied computationally in their N - and C-protected forms; Fig. 1 shows N -acetyl-L-Cys- N -methylamide (I) and N -formyl-L-

Cys-amide (II). $N$-Formyl-L-Ser-amide (III) has already been studied extensively (1-5) as a continuation of a general investigation including Gly $(6,7)$, Ala (6-8), Val (9), and Phe (10-12).

In many ways the cysteine residue is similar to serine; one therefore expects the $-\mathrm{CH}_{2}-\mathrm{SH}$ moiety of cysteine to be in-

[^0]Fig. 1. $\gamma_{\mathrm{L}}$ conformations of MeCO-Cys-NHMe (I), HCO-Cys$\mathrm{NH}_{2}$ (II), and HCO-Ser-NH2 (III). The numbering system of the atoms and the torsional angles $\omega_{0}, \omega_{1}, \phi, \psi, \chi_{1}$, and $\chi_{2}$ are shown in this figure.

volved in intramolecular hydrogen bonding similar to that demonstrated in Fig. 2 for the $-\mathrm{CH}_{2}-\mathrm{OH}$ group of serine.

Cysteine, a residue with a polar side chain, is often located on the surface of proteins, and thus is directly involved in various biochemical interactions. Cysteine can mediate structural changes, improve hydration of accessible area, or participate in intermolecular interactions. Thus, cysteine is frequently involved in a wide range of enzymatic reactions including those of cysteine proteases (13-15). In Scheme 1, a simplified mechanism of cysteine protease (HS-E-Im) is shown, where HS symbolizes the mercaptan side chain of a cysteine residue and Im denotes the imidazole moiety in the side chain of a histidine residue. The enzyme is not active at low pH due to protonation at Im , and it is also inactive at high pH due to deprotonation of the SH group. It is only active at neutral pH when internal proton transfer is possible from the SH group to Im.

A schematic mechanism for the hydrolysis of the peptide bond with the catalytic action of cysteine protease is shown in Scheme 2.

In addition to regular cysteine proteases, there are numerous other enzymes that contain free-sulfhydril groups. For example, there is a cysteine-containing enzyme called transglutaminase, which does not hydrolyze peptide bonds, but instead transfers an acyl group from one nitrogen to another. This field of study has recently been extensively reviewed (16). Vigorous theoretical investigations of this cysteine-containing pro-enzyme is currently being pursued by other research groups (17).

B

Scheme 1.

The full conformational space of compound I was recently explored by ab initio RHF/3-21G computations (18). On the Ramachandran hypersurface of four independent variables $E=f\left(\phi, \psi, \chi_{1}, \chi_{2}\right)$ (Fig. 1), 47 conformers were located instead of the expected $3^{4}=81$ stable structures. The relative stabilities of the various conformers were analyzed in terms of side-chain-backbone interactions covering both hydrogen bonding and charge-transfer types. These results indicated that the $\gamma_{\mathrm{L}}$-backbone conformation is the preferred form for this compound. In the present report, we have mainly focused our attention on the conformational intricacies of compound $\mathbf{I}$, while restricting the backbone conformation to its global minimum $\left(\gamma_{\mathrm{L}}\right)$. A comparative study using different levels of theory of compounds I-III was also carried out.

## Methods

## Conformational analysis

IUPAC-IUB (19) recommended the use of $0^{\circ} \rightarrow+180^{\circ}$ in the clockwise direction for rotation and $0^{\circ} \rightarrow-180^{\circ}$ for counter-clockwise rotation (Scheme 3). For side-chain torsions, this implied the following range: $-180^{\circ} \leq \chi_{1} \leq 180^{\circ}$ and $-180^{\circ} \leq \chi_{2} \leq 180^{\circ}$. On the Ramachandran map, the $-180^{\circ} \leq \phi \leq 180^{\circ}$ and $-180^{\circ} \leq \psi \leq 180^{\circ}$ cut is indicated by the square drawn in broken lines (Fig. 3).

But for the graphical presentation of the side-chain conformational potential-energy surface (PES), we used the traditional cut $\left(0^{\circ} \leq \chi_{1} \leq 360^{\circ}\right.$ and $\left.0^{\circ} \leq \chi_{2} \leq 360^{\circ}\right)$, similar to that previously suggested by Ramachandran and Sasisekharan (20).

## Molecular computations

Initially, the nine side-chain conformations of cysteine in its $\gamma_{\mathrm{L}}$-backbone conformation were determined using the topologically probable set of conformers as predicted by multidimensional conformational analysis (MDCA) (21-23).

## Scheme 2.

Table 1. Total energy values (Hartree) of the component molecules for isodesmic reactions.

Scheme 3.

To investigate the side-chain-backbone conformational interaction effects, calculations were performed on compounds I and II using the Gaussian 94 (24) program at the RHF/321G (25) level of theory. This lower level is suitable for the purpose of comparing the present results with those obtained for serine $(1,2)$, even though the current trend is to rely on larger basis sets at a higher level of theory $(8,26)$. For this reason, geometry optimizations were also carried out for compounds I and II at the B3LYP/6-31G(d,p) level of theory.

## Stabilization energies

The stabilization energies were calculated with respect to $\gamma_{L^{-}}$as well as to $\beta_{\mathrm{L}}\left(\mathrm{C}_{5}\right)$-backbone conformation of N - and C-protected glycine $(9,27)$ using the following isodesmic (same number of the same type of bonds) reaction, where P and Q may be H (II) or $\mathrm{CH}_{3}$ (I) and $\mathrm{R}=\mathrm{CH}_{2}-\mathrm{SH}$ :

## P-CONH-CH2 $-\mathrm{CONH}-\mathrm{Q}+\mathrm{CH}_{3}$ - $\mathrm{R} \rightarrow$ P-CONH-CHR-CONH-Q $+\mathrm{CH}_{3}-\mathrm{H}$

 reference conformation $\gamma_{L}$ or $\beta_{L}$ conformation XThe stabilization energy may be calculated as follows:

$$
\begin{aligned}
& \Delta E_{\text {stabil }}=\left\{E[\mathrm{P}-\mathrm{CONH}-\mathrm{CHR}-\mathrm{CONH}-\mathrm{Q}]_{X}+E\left[\mathrm{CH}_{3}-\mathrm{H}\right]\right\} \\
&\left.-\left\{E\left[\mathrm{P}-\mathrm{CONH}-\mathrm{CH}_{2}-\mathrm{CONH}-\mathrm{Q}\right]_{\gamma_{\mathrm{L}}} \text { or } \beta_{\mathrm{L}}+\mathrm{CH}_{3}-\mathrm{R}\right]\right\}
\end{aligned}
$$

The energy values of the components are summarized in Table 1.

The results of the structure optimizations, namely, geometrical parameters, total energies, relative energies, and stabilization energies, are given in Tables $2-4$. The total energies are given in Hartrees, and the relative energies and

Fig. 3. Topological representation of the Ramachandran map for an N - and C-protected amino acid P-CONH-CHR-CONH-Q (P and Q may be H or $\mathrm{CH}_{3}$ ) showing two full cycles of rotation: $-360^{\circ} \leq \phi \leq+360^{\circ} ;-360^{\circ} \leq \psi \leq+360^{\circ}$. The central box, denoted by broken line, represents the cut suggested by the IUPAC convention. The four quadrants denoted by solid lines are the conventional cuts. Most peptide residues exhibit nine unique conformations labeled as $\alpha_{D}\left(\alpha_{\text {LEFT }}\right), \varepsilon_{\mathrm{D}}, \gamma_{\mathrm{D}}\left(\mathrm{C}_{7}^{\text {ax }}\right), \delta_{\mathrm{L}}\left(\beta_{2}\right), \beta_{\mathrm{L}}\left(\mathrm{C}_{5}\right)$, $\delta_{\mathrm{D}}\left(\alpha^{\prime}\right), \gamma_{\mathrm{L}}\left(\mathrm{C}_{7}^{\mathrm{eq}}\right), \varepsilon_{\mathrm{L}}$, and $\alpha_{\mathrm{L}}\left(\alpha_{\text {RIGHT }}\right)$.

stabilization energies in $\mathrm{kcal} \mathrm{mol}^{-1}$ (using the conversion factor: 1 Hartree $=627.5095 \mathrm{kcal} \mathrm{mol}^{-1}$ ). The numbering system used for $N$-acetyl-L-cysteine- $N$-methyl amide ( P $=\mathrm{Q}=\mathrm{Me})$ and $N$-formyl-L-cysteinamide $(\mathrm{P}=\mathrm{Q}=\mathrm{H})$ is shown in Fig. 1.

## Topological analysis of electron density

The topology of the electron density was analyzed using AIM (atoms in molecules) (28). In this analysis, the gradient $[\nabla \rho(\mathrm{r})]$ and the Laplacian $\left[\nabla^{2} \rho(\mathrm{r})\right]$ play important roles. A critical point of the electron density along the line of two interacting atoms in a molecule is called the bond critical point $(\mathrm{BCP})$, where $\nabla \rho(\mathrm{r})=0$.

Fig. 4. (a) Backbone conformers of all 10122 Cys residues taken from 974 non-homologous proteins (31). Using their backbonedihedral parameters, all of the above Cys residues were plotted on a $[\phi, \psi]$ map. (b) Locations of calculated ab initio RHF/321G MeCO-Cys-NHMe backbone conformers (18) on a $[\phi, \psi]$ map.

The bond path is made up of a pair of gradient paths, originating at a BCP and terminating at a neighbouring nuclei. The necessary condition for two atoms to be bonded to each other is that their nuclei must be linked by a bond path. The bond path is regarded as "a universal indicator of bonded interaction" (29). The method is widely used for proving the existence of hydrogen bonds (30).

## Results and discussion

The comparison of structural parameters from experimental databases (X-ray and NMR) with the ab initio (RHF/3$21 \mathrm{G})$ results is an excellent validation of the computed results. Thus, the comparison of relative energies and the relative probabilities of conformers using a non-homologous database is a possibility for this cross-validation. Let us truncate the backbone of a protein into building units, e.g.,

Fig. 5. The possible nine molecular conformations of MeCO-Cys-NHMe. The two conformations that are crossed over are not minima, the remaining seven were located during HF/3-21G optimization.

Fig. 6. Relative energies ( $\mathrm{kcal} \mathrm{mol}^{-1}$ ) obtained for the different conformations of compounds I-III.

amino acid diamides. We will assume that the probability of conformers in proteins depends only on its relative energy. This is a model where several stabilizing factors are neglected, such as inter-residue interactions, long-range effects, and hydration. By acknowledging the limitations of this approach, it is possible to correlate the relative energy of a conformer and the relative probability of the same backbone structure in an ensemble of proteins with known X-ray and NMR structures.

Using a recent (February 2002) X-ray- and NMRdetermined protein data set of non-homologous proteins

Fig. 7. Correlation of relative energies computed at DFT and HF/3-21G levels of theory for MeCO-Cys-NHMe (top), HCO-Cys- $\mathrm{NH}_{2}$ (centre), and HCO-Ser- $\mathrm{NH}_{2}$ (bottom).

(31), a population-distribution map was generated (Fig. 4a). The backbone conformers of 10122 Cys residues, found in a total of 974 proteins, were plotted, showing $\phi$ vs. $\psi$ values (Fig. 4a). The overall appearance of the Ramachandran surface is similar to other previously reported Ramachandran maps (Phe (12) and Ser (32)). Thus Cys shows an "average conformational character."

To perform a comparison between calculated and observed backbone conformers, an additional plot was made with the RHF/3-21G results (Fig. 4b). Comparing these data a promising overall similarity emerged. In the highly populated extended $\beta$-strand $\left(\beta_{L}\right)$ and inverse $\gamma$-turn $\left(\gamma_{L}\right)$ region, the location of the RHF/3-21G model structures and the largest probability of experimental- backbone conformers taken from the protein databases are similar (zone denoted with dotted lines in Fig. 4).

It should be noted that the seven $\gamma_{\mathrm{L}}$ conformers and the seven $\beta_{\mathrm{L}}$ conformers, together with the three $\delta_{\mathrm{L}}$ conformers, are a subgroup formed by the most stable conformers of compound I. This low-energy region of the Ramachandran

Fig. 8. Correlation of torsional angles computed at DFT and HF/3-21G levels of theory for MeCO-Cys-NHMe (top), HCO-Cys- $\mathrm{NH}_{2}$ (centre), and HCO-Ser- $\mathrm{NH}_{2}$ (bottom).

map (often quoted as the $\beta$ region) is also the most dense area if X-ray- and NMR-determined main-chain probabilities are investigated. Such a correlation permit us to assume that if the diamide model is relevant to the description of main-chain folding of proteins, then the most stable conformers should have the lowest energy.

On the basis of the above results, in the present study we focused our attention on the conformational intricacies of the highly preferred backbone conformation of compounds I and II, this being the $\gamma_{\mathrm{L}}$ form.

## Conformational study

The nine side-chain conformations, topologically predicted on the basis of MDCA, are depicted for compound I in Fig. 5. Two of the structures ( $g^{+} g^{-}$and $a a$ ) are crossed out, since they were not found. On the basis of the $E=f\left(\chi_{1}, \chi_{2}\right)$ potential-energy surface (PES) generated for HCO-Ser-NH2 (1), one may anticipate that these minima were eliminated due to a high-energy region or "mountain ridge" formed along the disrotatory diagonal axis. The other seven minima,

Fig. 9. Structures located on the side-chain PES of the $\gamma_{\mathrm{L}}$-backbone conformations of N - and C -protected serine and cysteine. The stabilization energies ( $\Delta E_{\text {stabil }}$, kcal $\mathrm{mol}^{-1}$ ) exerted by the side chain with respect to the glycine residue in its $\gamma_{\mathrm{L}}$ conformation are shown in brackets.

Fig. 10. Spectrum of conformational dependence of the sidechain stabilization energy on the $\gamma_{\mathrm{L}}$-backbone conformation of protected Ser and Cys.

however, were successfully geometry optimized at the HF/3-21G level of theory (Table 2).

The structures of I and II were geometry optimized at the HF/3-21G level of theory and further optimized at the B3LYP/6-31G(d,p) level of theory (Tables 2 and 3). Their relative energy values are shown in a topological fashion in Fig. 6. For full comparison, HCO-Ser-CONH 2 (III) conformations were also evaluated at the B3LYP/6-31G(d,p) level of theory (Table 4).

The reliability of the HF/3-21G level of computations can be investigated here since we have results from HF/3-21G and B3LYP/6-31G(d,p) levels. The relative energies ( $\Delta E_{\mathrm{rel}}$ ) of compounds I-III, computed at the two levels of theory, are compared in Fig. 7. Since the global minimum on the relative energy scale is, by definition, always zero, in order for the fitted line to pass over the origin, a $y=m x$ equation was fitted to the data points. While the slopes of the fitted lines are never unity, it is clear that the HF/3-21G results reproduce the trend quite well.

In addition to the relative stabilities, the accuracy of the key torsional angles (in the present case, $\phi, \psi, \chi_{1}, \chi_{2}, \omega_{0}$, and $\omega_{1}$ ) is of great importance. The correlation of the above torsional angles computed at two levels of theory for com-

Fig. 11. Relative side-chain stabilization energy values of various amino acids in the $\gamma_{\mathrm{L}}$-backbone conformation.

pounds I-III are shown in Fig. 8. The least-square fit was of the type $y=m x+b$. For the cysteine and serine residues, $m$ is not unity nor is $b$ zero. The fitted lines, however, suggest a surprisingly good correlation.

## Stabilization energies

Stabilization energies emerging from side-chain interaction with the backbone are traditionally calculated (7, 27) with respect to the global minimum, i.e, the $\gamma_{\mathrm{L}}$ conformation. It has been noted recently (33), however, that during the cistrans isomerization process, the $\gamma_{\mathrm{L}}$ conformation may disappear for at least some of the amino acids. In other words, the $\gamma_{\mathrm{L}}$ conformer does not exist as a minimum-energy conformation on some of the cis-Ramachandran maps. For this reason, an alternative backbone conformation $\beta_{\mathrm{L}}$ was selected for calculating the stabilization energy $\left(\Delta E_{\text {stabil }}\right)$. The method of calculation, as outlined in the Computational methods section, is the same, but instead of the $\gamma_{\mathrm{L}}$ conformation of glycine, the $\beta_{\mathrm{L}}$ conformation is chosen as the reference conformation. Such a new standard may be important in the future, when an ab initio peptide database may include both cis and trans peptides. Nevertheless, the $\Delta E_{\text {stabil }}\left(\gamma_{\mathrm{L}}\right)$ values are more practical if we wish to make comparisons with previously reported values.

Figure 9 compares $\Delta E_{\text {stabil }}\left(\gamma_{L}\right)$ values for compounds I-III. It is reassuring to see that the effect of the side-chain stabilization is not affected substantially if we change the protecting group from formyl to acetyl at the nitrogen end and from amide to methylamide at the carboxyl end.

The $N$-acetyl and $N$-methyl amide protecting groups of cysteine $\mathbf{I}$ are stabilized by the $\mathrm{CH}_{2}-\mathrm{SH}$ side chain by $\sim 0.16 \mathrm{kcal} \mathrm{mol}^{-1}$ more when compared with the same side chain stabilizing the N -formyl-cysteinamide (II) backbone. There are, however, marked differences when the oxygen is changed to sulfur in the side chain. Undoubtedly, such a change between serine and cysteine, as seen in Fig. 9, is also present in the relative energy values ( $\Delta E_{\text {rel }}$ ) presented in Fig. 6. The stabilization energy values are not only numerically different for Ser and Cys but they are also decreased

for Cys and increased for Ser, as seen in Fig. 10. When the global minima are compared, the side chain of Cys is stabilizing the backbone more than that of Phe but less than those of Asp and Ser. Such a "spectrum" of side-chain stabilization is presented in Fig. 11.

The size difference between $O$ and $S$ could play a major role in producing such remarkable energy differences. Additionally, since both make the same kinds of hydrogen bonds it is reasonable to assume that the Ser side chain is more favourably stabilizing than the Cys side chain because hydrogen bonds to and from oxygen atoms are stronger than sulfur atoms. This result is not surprising, since methanol is a liquid and methanethiol is a gas. This is in agreement with the ordering of the $g^{+} g^{+}, g^{+} a$, and $a g^{-}$conformations discussed in the next section.

## Intramolecular interactions

The three types of intramolecular interactions, which may occur in the various conformers of cysteine, are shown in

Fig. 12. The characteristic distances and angles, as well as the classification of interactions, are summarized in Table 5. Only the $g^{+} a$ conformer has a heteroatomic distance that is short enough to suggest an $\mathrm{O} \rightarrow \mathrm{S}$ charge-transfer interaction.

In agreement with the data presented in Table 6, AIM analysis revealed that extensive side-chain-backbone intramolecular hydrogen-bonding-type interactions exists in three of the seven conformers. These were found to be $g^{+} g^{+}$, $g^{+} a$, and $a g^{-}$. Taking into account the distances and angles, however, we might consider that five of the seven $\gamma_{\mathrm{L}}$ conformations are stabilized by hydrogen bonding interactions (Table 5).

The $g^{+} g^{+}$conformer has the greatest number of hydrogen bonds, so it is not surprising that it emerges as being the global minimum. In addition to the hydrogen bond, which is characteristic of the seven-member ring of the $\gamma_{\mathrm{L}}$-backbone conformation, there are two additional hydrogen bonds corresponding to side-chain $\rightarrow$ backbone ( $\mathrm{C}=\mathrm{O} \cdots \mathrm{H}-\mathrm{S}$ ) and

Bond paths are denoted by lines, bond critical points (BCPs) are denoted by black dots, ring critical points (RCPs) are denoted by open triangles, and the nuclei are denoted by crosses.

## Conclusions

In summary, we found seven different conformations for the side chain of compounds I and II when the backbone is in $\gamma_{L}$ form. These results suggest that the side-chain stabilization is not substantially affected if we change the protecting group from formyl to acetyl at the nitrogen end and from amide to methylamide at the carboxyl end. In contrast, noticeable differences were found when comparing the conformational intricacies of compounds II and III: only six different conformations were obtained for compound III and the order of preference is also different. DFT calculations proved that polar side chains are able to interact with a peptide backbone, eliminating some otherwise legitimate minima through unfavourable backbone and side-chain torsional-angle combinations. The comparative study between compounds II and III illustrates this point very well. On the basis of our results, we might assume that the strength of hydrogen bonding involved is responsible for the different conformational behavior obtained for these compounds. On the other hand, it is interesting to note that both levels of theory (HF/3-21G and B3LYP/6-31G(d,p)) displayed closely related results indicating that $\mathrm{HF} / 3-21 \mathrm{G}$ calculations are satisfactory to use in exploratory conformational studies.
