**HIGHLIGHTS**

- The seasonal variation of the macrobenthic community of Caleta Valdés were reported
- Highest abundance were found in Spring-Summer with a predominance of biodiffusors
- A deeper advective sediment transport was demonstrated in Spring-Summer
- *Ex situ* and *in situ* sediment reworking measurements showed similar results
- The experimental procedure for *ex situ* ecotoxicological studies was validated

4  
5                   **Abstract**

6                   Caleta Valdés (CV) is a coastal lagoon of the Patagonian Atlantic coast located  
7                   in the Península de Valdés declared as Humanity Mundial Patrimony due to its  
8                   remarkable biodiversity, ecosystemic richness, and pristine state. Marine  
9                   mammal populations are well documented in this area but few studies have  
10                  been carried out on the local macrobenthic communities. The goals of this study  
11                  were (a) to evaluate for the first time the seasonal variation of the structure and  
12                  activity (i.e., sediment reworking) of the intertidal macrobenthic communities of  
13                  CV, and (b) to validate an *ex situ* experimental protocol for future  
14                  ecotoxicological studies. To do so, sedimentary (granulometry, water content,  
15                  and organic matter) and biological (macrobenthic assemblages, biodiffusive-like  
16                  and advective sediment reworking components) parameters were analyzed  
17                  using a combination of *in situ* and *ex situ* measurements. Overall, polychaete  
18                  and crustacean dominated the macrobenthic community. The highest  
19                  abundances were found in Spring-Summer along with a predominance of  
20                  biodiffusors versus conveyors. *Ex situ* and *in situ* measurements demonstrated  
21                  similar results, thus allowing validation of an *ex situ* experimental procedure for  
22                  macrobenthic community and functioning studies. In addition, these results  
23                  provide a first baseline of benthic information on CV that will be helpful to  
24                  monitor the effects of potential pollution in Patagonian coastal systems.

**26 Keywords**

27 Biodiversity, bioturbation, sedimentary matrix, soft-bottom macrofauna,  
28 protected areas.

29

**30 1. Introduction**

31 The Patagonian coast is about 3000 kilometers long with a high value in terms  
32 of biodiversity (Esteves and Arhex, 2009). This coast is used by migratory birds  
33 and marine mammals to rest, feeding and mating (Yorio, 2009). Moreover, it  
34 includes zones of reproduction and breeding of fish, crustaceans, and mollusks  
35 sustaining one of the most productive temperate marine ecosystems in the  
36 world (Vázquez, 2004). As in other marine coastal environments, the food webs  
37 are mainly sustained by phytoplankton (Smetacek, 1999). Particularly, in these  
38 coasts, upwelling phenomena increase primary production (Acha et al., 2004).  
39 Due to its remarkable biodiversity and ecosystemic richness, big areas of this  
40 coast have a special protection status (e.g. Península de Valdés was  
41 established as Humanity Mundial Patrimony in 1999, North Zone San Jorge gulf  
42 was defined as Patagonian Austral Inter-jurisdictional Marine Coastal Park in  
43 2007 and Punta Tombo as Natural Protected Area in 1979, among others).  
44 Despite these protection measures, there are diverse and growing  
45 anthropogenic activities constituting a direct threat to the ecosystem. Therefore,  
46 studies about the seasonal dynamics of the macrobenthic communities  
47 constituting a particular interest at ecological level but also for integrated coastal  
48 zone management purposes.

Indeed, the soft-bottom benthic organisms play a key role in nutrient cycles, pollutant metabolism, dispersion, and burial of the organic matter and secondary production processes (Hopkinson et al., 1999; Snelgrove, 1998). These organisms have reduced mobility (Pearson and Rosenberg, 1978; Teixeira et al., 2012) and therefore they are highly sensitive to the physical and chemical changes of the sediment matrix (Dauvin et al., 2010; Muniz et al., 2005). For this reason, this group of organisms is useful as an indicator of ecological state in impacted sites and/or in monitoring programs (e.g. Teixeira et al., 2012). Through the excavation, burrow ventilation, and/or mud and organic matter ingestion (Taghon and Greene, 1992), they induce the transport of particles (sediment reworking) and fluids also known as bioturbation (Kristensen et al., 2012). Community bioturbation is a good integrator of macrofaunal functioning as it incorporates various aspects of behavior (e.g. feeding, locomotion, burrow building) and may vary depending on the community structure and local heterogeneity (Solan et al., 2019). Differences in bioturbation over time may also reflect the abiotic and/or biotic changes of not only the benthic but also the pelagic ecosystem. Particularly, bioturbation affects processes such denitrification (Gilbert et al., 2003), nitrification (Aller et al., 1998), sulfate reduction (Canavan et al., 2006), benthic fluxes (Aller and Aller, 1998; Mermillod-Blondin et al., 2005; Michaud et al., 2005; Mortimer et al., 1999) and microbe dynamics (Goñi-Urriza et al., 1999; Papaspyrou et al., 2006).

Reworking organisms can be classified into functional groups based on the different ways in which the organisms behave and on the resulting transport of

1 75 particles within the sedimentary column. According to Kristensen et al. (2012),  
2 76 these organisms can be differentiated into biodiffusors, upwards and downward  
3  
4 77 conveyors, and regenerators. Biodiffusors are species whose activities produce  
5  
6 78 a local, constant, and random mixture of sediment over short distances.  
7  
8 79 Upwards and downward conveyors are species vertically distributed that  
9  
10 80 respectively feed head down and deposit its dregs in the surface of the  
11  
12 81 sediment or inversely, and finally the regenerators, excavator species that  
13  
14 82 transfer the sediment from the bottom to the surface. In ecosystems, the  
15  
16 83 complex communities are then able to generate various patterns and intensities  
17  
18 84 of sediment reworking depending on their functional composition (e.g. Duport et  
19  
20 85 al., 2007). Moreover, it can be modulated by the environmental conditions via  
21  
22 86 changes in organisms behavior. For example, the burrowing polychaetes  
23  
24 87 *Hediste diversicolor* can switch from deposit-feeding to filter-feeding if the  
25  
26 88 phytoplankton concentration is high enough (Riisgård, 1994) and *Alitta virens*  
27  
28 89 has been shown to have a temperature dependence of sediment reworking  
29  
30 90 activity (Ouellette et al., 2004).

41 92 The goals of this study were (a) to evaluate for the first time the seasonal  
42  
43 93 variation of the structure and the activity (i.e., sediment reworking) of the  
44  
45 94 intertidal macrobenthic communities of Caleta Valdés and, (b) to validate an *ex*  
46  
47 95 *situ* experimental protocol for future ecotoxicological studies.

99 Caleta Valdés (CV) is a north-south-oriented coastal lagoon located at the  
100 eastern side of Península Valdés. This is 30 km long and has its mouth at the  
101 southern end where the water exchange is produced at two and four nudes of  
102 velocity. A gravel bank limits the lagoon, generating a channel of 200 m width  
103 and a mean depth of 5 m. The enclosed north zone presents a marsh that cover  
104 a 25% of the total surficial of the system (Esteves et al., 1993). The tidal  
105 regimen is semidiurnal with a mean high of 5 m. The sampling site for the  
106 experimentation was chosen in the muddy north continental zone of CV  
107 ( $42^{\circ}15'53''$  S,  $63^{\circ}40'50''$  W; Figure 1) due to its macrofauna richness and the  
108 absence of anthropogenic pollution. Currently, this natural reserve is protected  
109 of human activities so that strict control is carried out on touristic and smaller  
110 productive activities, which are developed in the area.

## 111 2.2. Sampling

112 Sediment cores were sampled by hand in autumn (April 2011), winter (July  
113 2011), spring (November 2011), and summer (February 2012) using 10 cm  
114 diameter and 25 cm length PVC cores, in agreement with previous bioturbation  
115 studies (Ferrando et al., 2015; Hedman et al., 2011; Quintana et al., 2007;  
116 Timmermann et al., 2002). At each season, at low tide, eight cores were  
117 vertically and randomly pushed down to 20 cm sediment depth approximately.  
118 Then, for *ex situ* experiments, four of them were immediately collected by hand  
119 and transported to the laboratory. The other four cores were embedded in the  
120 sediments for *in situ* assessments. In addition to sediment sampling, 60 L of  
121 seawater were also collected in plastic containers to be used for the *ex situ*  
122 experiments. This procedure was applied for each studied season.

124

125 *2.3. Incubation conditions*126 *2.3.1. In situ* experiments

127 In order to assess biological reworking activity, in each sediment core, 4 g of  
128 luminophores (inert fluorescent particles, Duport et al., 2007) of two sizes and  
129 colors (pink: 65-125  $\mu\text{m}$ ; green: 125-355  $\mu\text{m}$ ) were homogeneously spread at  
130 the sediment surface at initial time (T=0 day). Luminophores sizes were  
131 selected according to the two major size distribution modes of sedimentary  
132 particles in the studied site (Sturla Lompré et al., 2018). After 13 days of *in situ*  
133 incubation, the cores were withdrawn and carried out to the laboratory. Then,  
134 the sediment cores were sliced to provide 0.5 cm thick sediment layers from the  
135 surface to 2 cm depth and 1 cm thick sediment layers from 2 to 17 cm depth.  
136 Each sediment slice was separated in four equal parts that were randomly  
137 distributed to perform the different analyses.

138

139 *2.3.2. Ex situ* experiments

140 Similarly, for each season, the four cores containing the sediments sampled at  
141 CV were distributed in a 56 L tank that was then filled until the cores were totally  
142 submerged with the seawater collected the same day in the same sampling  
143 station. To assess biological reworking activity in a no water flow system where  
144 no hydrodynamic loss of tracers could occur, in each sediment column, 2 g of  
145 the two types of luminophores (pink: 65-125  $\mu\text{m}$  and green: 125-355  $\mu\text{m}$ ) were  
146 homogeneously spread at the sediment surface at the initial time (T=0 day).  
147 The system was kept continuously aerated (air bubbling). Sediment cores were  
148 incubated for 13 days at a similar ambient temperature to the *in situ*

149 assessment. Then, they were manually collected and processed identically as  
150 for the *in situ* experiments.

151

## 152 2.4. Analytical procedures

### 153 2.4.1. Sediment characterization

154 A quarter of each sediment slice was used to determine sediment granulometry  
155 (only in autumn 2011) by laser beam diffraction (Partica LA-950; HORIBA  
156 Instruments, Inc.), and for the four seasons, water content and organic matter  
157 by oven drying at 105 °C during 24 h and muffle furnace ignition at 450 °C  
158 during 4 h, respectively. Eight granulometry fractions were obtained: fine silt < 6  
159 µm, medium silt 6-20 µm, coarse silt 20-60 µm, very fine sand 60-125 µm, fine  
160 sand 125-200 µm, medium sand 200-600 µm, coarse sand 600-1000 µm, and  
161 very coarse sand 1000-2000 µm.

162

### 163 2.4.2. Macrobenthic communities

164 The remaining three quarters of each sediment slice were fixed and dyed with a  
165 neutralized 4% formaldehyde solution and Rose Bengal colorant, respectively.  
166 Then, the samples were sieved, first with a 500 µm mesh and then with a 44 µm  
167 mesh. The sediment retained in the first mesh was preserved in ethanol 70% for  
168 the identification and counting of the macrobenthic organisms. The sorting of  
169 organisms (for the four seasons) was done to the lowest possible taxonomic  
170 level using stereoscopic and optic microscopes in the laboratory with reference  
171 material and dichotomous keys (Banse and Hobson, 1974; Blake and Ruff,  
172 2007; Hartman, 1968, 1969; Orensanz et al., unpublished data, among others).  
173 Only the whole organisms or anterior fragments of each taxon were recorded.

174

## 175 2.4.3. Bioturbation

176 The sediments retained in the 44  $\mu\text{m}$  mesh were used (see above) to quantify  
177 sediment reworking. The sediments were homogenized and subsampled to  
178 quantify the luminophores percentage using a microplate reader (Biotek,  
179 Synergy Mx) at  $\lambda_{\text{ex}}/\lambda_{\text{em}}$ : 460/500 and 565/602 nm for the pink and green  
180 luminophores, respectively (Majdi et al., 2014). For each sediment column at  
181 the four seasons, we obtained the vertical luminophores profile at the  
182 experimental final time (13 days) from the percentage of luminophores found in  
183 each layer concerning the total amount in the core. The quantification of  
184 sediment reworking was then evaluated from the distributions of luminophores  
185 by the gallery-diffusor model (François et al., 2002). This model allows  
186 describing both the biodiffusion-like transport ( $D_b$  coefficient) due to the  
187 continuous displacement of the tracers and the nonlocal advective displacement  
188 of the tracers ( $r$  coefficient). The best fit between observed and modeled tracer  
189 distribution with depth (i.e., producing the best  $D_b$  and  $r$  coefficients couple) was  
190 estimated by the least-squares method (Gilbert et al., 2007).

191

## 192 2.4.4. Statistical data analysis

193 Variation between seasons (autumn, winter, spring and summer) and  
194 experimental conditions (I: *in situ* and E: *ex situ*) of water content and organic  
195 matter (OM) were evaluated by core through two-way ANOVA considering  
196 seasons and conditions as fixed factors (n=32) (Statistica, version 7). A square  
197 root transformation was applied to satisfy the homogeneity of variances

198 assumption. The differences between pairs of seasons and conditions were  
199 tested through Tukey test for multiple mean comparisons (Statistica, version 7).

200

201 A comparison of the mean abundance by core of dominant taxa between  
202 seasons and I and E experimental conditions were evaluated through two-way  
203 ANOVA considering seasons and conditions as fixed factors (n=32) (Statistica,  
204 version 7). A square root transformation was applied to satisfy the homogeneity  
205 of variances assumption. The differences between pairs of seasons and  
206 conditions were tested through Tukey test for multiple mean comparisons  
207 (Statistica, version 7).

208

209 Biological data analyses were performed using the software package PRIMER  
210 7.0 (Plymouth Marine Laboratory, UK). The sorting using the total abundance of  
211 each taxa by core recorded in the I and E experiments at the four seasons was  
212 carried out with a nonmetric multidimensional scaling (nMDS) analysis (Bray-  
213 Curtis index; group average link; square root). In addition, a Permutational  
214 Multivariate Analysis of Variance (PERMANOVA) was applied to assess the  
215 effect of the seasons, I and E experimental conditions, and the interaction  
216 between both factors (Bray-Curtis index; fourth root and 9999 permutations)  
217 (PRIMER v7). A Pair-wise PERMANOVA was applied to analyze the significant  
218 differences between seasons and conditions (Bray-Curtis index; fourth root and  
219 9999 permutations) (Anderson et al. 2008). Moreover, Specific richness (S),  
220 total abundance (N), and the Shannon diversity index ( $H'$ ) were calculated by  
221 layer and core (I and E) at the four seasons. Variation of each biological  
222 parameter between seasons and conditions was evaluated through two-way

223 ANOVA considering seasons and conditions as fixed factors (n=32) (Statistica,  
224 version 7). The differences between pairs of seasons and conditions were  
225 tested through Tukey test for multiple mean comparisons.

226

227 A comparison of the depth distributions of the luminophores for the two particles  
228 range sizes (pink and green) and the bio-diffusion ( $D_b$ ) and bio-advection ( $r$ )  
229 coefficients calculated for each experimental condition (I and E) was performed  
230 through the non-parametric Kruskal-Wallis one-way analysis of variance by  
231 ranks (Kruskal and Wallis, 1952) (Statistica, version 7). Moreover, a one-way  
232 ANOVA was applied to test the differences between seasons (n=16). The  
233 differences between pairs of seasons were tested through Fisher LSD test for  
234 multiple mean comparisons (Statistica, version 7). A Kruskal-Wallis and Pair-  
235 wise Multiple Comparisons analysis were carried out to test the differences as a  
236 non-parametric alternative due to lack of homogeneity of variances of data in  
237 some cases.

238

### 239 **3. Results**

#### 240 *3.1. Characterization of the sediment*

241 The granulometry profiles were similar for the *in situ* and the *ex situ* sediments  
242 showing a predominance of medium sand (200-600  $\mu\text{m}$ ) (Figure 2). Moreover,  
243 the fine fractions (< 200  $\mu\text{m}$ ) were highest at the first two centimeters of the  
244 sedimentary columns. Regards *in situ* sediments, the maximum percentages of  
245 water content ( $58.5 \pm 8.2\%$ ) and organic matter (OM) ( $1.7 \pm 0.1\%$ ) were  
246 recorded in the first layer (0-0.5 cm) in winter and autumn, respectively (Online  
247 Resource 1). In spring, the maximum percentages of water content ( $48.5 \pm$

248 19.6%) and OM ( $1.3 \pm 0.2\%$ ) were found in the fourth layer (1.5-2 cm) and the  
249 first layer (0-0.5 cm), respectively. In summer, the maximum percentages of  
250 water content ( $33.3 \pm 0.8\%$ ) and OM ( $0.9 \pm 0.0\%$ ) were recorded in the second  
251 (0.5-1 cm) and second and third layers (0.5-1.5 cm), respectively. These  
252 patterns were similar to those recorded in *ex situ* conditions (Online Resource  
253 1). Comparing seasons and experimental conditions (I and E), percentages of  
254 water content did not show significant effect of the interaction of these factors  
255 (Two-way ANOVA,  $p = 0.15$ ,  $n = 32$ ) but highly significant effect of each factor  
256 ( $p < 0.01$ ,  $n = 16$ ). Percentages of water content recorded in I and E conditions  
257 for winter and summer were similar (Tukey test  $p = 0.23$  and  $p = 0.06$ ;  $n = 8$ ,  
258 respectively). Contrary, in autumn and spring, this parameter was significantly  
259 higher I than E (Tukey test  $p < 0.01$ ;  $n = 8$ ) (Figure 3). Moreover, in I conditions,  
260 water content showed not significant differences (Tukey test  $p > 0.05$ ;  $n = 16$ )  
261 among autumn, winter and spring, but did (Tukey test  $p < 0.01$ ;  $n = 16$ ) in  
262 summer compared to other seasons. By contrast, in E conditions, in winter  
263 water content was significantly higher (Tukey test  $p < 0.01$ ;  $n = 16$ ) than in other  
264 seasons (Figure 3). Percentages of OM showed significant effect of the  
265 interaction season and experimental condition (Two-way ANOVA,  $p = 0.01$ ,  $n =$   
266  $32$ ) and just significant effect of season ( $p < 0.01$ ,  $n = 16$ ). Only significant  
267 differences between I and E conditions were recorded in spring ( $p = 0.026$ ,  $n =$   
268  $8$ ). Comparing seasons, at both conditions, the highest values were recorded in  
269 autumn with significant differences (Tukey test  $p < 0.01$ ;  $n = 16$ ) from the rest  
270 seasons. At I conditions, OM significant differences ( $p < 0.01$ ;  $n = 16$ ) were  
271 between winter and spring from summer; conversely, E conditions presented

272 significant differences ( $p < 0.01$ ,  $n = 16$ ) between winter from spring and  
273 summer (Figure 3).

274

### 275 3.2. Macrobenthic communities

276 A total of 27 taxa (I and E conditions) were found in CV including sixteen taxa of  
277 crustaceans, nine taxa of polychaetes, and one taxon of oligochaetes and  
278 nemerteans (Table 1). Mean abundance of the six most dominant taxa ( $> 4.8\%$ )  
279 are shown in Figure 4. All taxa except *Axiiothella* sp. were more abundant in the  
280 spring-summer period. This was pronounced in summer for the polychaete  
281 *Exogone molesta* (Syllidae), the most abundant species (37.4% of total  
282 macroinfauna). In addition, the two-way ANOVA showed only for *Scoloplos* sp.  
283 and *E. molesta* highly significant ( $p = 0.00$ ,  $n = 32$ ) and significant ( $p = 0.02$ ,  $n =$   
284 32) effect of the interaction (season and experimental condition) and I and E  
285 factor, respectively. On the contrary, all the dominant taxa showed a highly  
286 significant effect ( $p = 0.00$ ,  $n = 32$ ) of the season factor. Particularly, the  
287 differences between pairs of seasons showed not significant differences (Tukey  
288 test  $p > 0.05$ ;  $n = 32$ ) for *Axiiothella* sp. and between autumn and winter all the  
289 cases (Tukey test  $p > 0.05$ ;  $n = 32$ ). Moreover, abundance recorded in these  
290 seasons showed highly significant differences (Tukey test  $p < 0.01$ ;  $n = 32$ ) with  
291 spring and summer, which were similar in most cases (Figure 4). Finally, only  
292 for *E. molesta* in spring were detected significant differences (Tukey test  $p <$   
293 0.05;  $n = 32$ ) between experimental conditions.

294

295 The nMDS showed a good representation (stress = 0.15) and grouped spring  
296 and summer samples, which were located on the opposite side of winter

1 297 samples. Autumn samples were in an intermediate position close to spring-  
2 298 summer it. In addition, I and E faunistic composition were similar all the seasons  
3  
4 299 (Figure 5). Moreover, the interaction between the factors season and  
5  
6 300 experimental condition (I and E) were not significant (PERMANOVA,  $p > 0.01$ )  
7  
8 301 meanwhile the effect of each factor was it ( $p < 0.01$ ) (Table 2). The Pair-wise  
9  
10 302 PERMANOVA showed highly significant differences ( $p < 0.01$ ) between all the  
11  
12 303 seasons in both experimental conditions (I and E) meanwhile the differences  
13  
14 304 between I and E were highly significant ( $p < 0.01$ ) only in spring.  
15  
16  
17  
18  
19  
20

21 305  
22 306 Vertical profiles of the community parameters (S, N and H') showed a similar  
23  
24 307 trend for the four seasons with maximum values in the first five centimeters of  
25  
26 308 the sedimentary columns and a decrease with depth (Figure 6). The two-way  
27  
28 309 ANOVA for each community parameter showed only significant effect of the  
29  
30 310 interaction (season and experimental condition) for H', meanwhile the effect of  
31  
32 311 both factors were significant for S and H' ( $p < 0.01$ ,  $n = 32$ ) and just factor  
33  
34 312 season for N ( $p < 0.11$ ,  $n = 32$ ). Regarding the differences between  
35  
36 313 experimental conditions (I and E), significantly higher values I than E were  
37  
38 314 recorded in spring H' (Tukey test  $p = 0.023$ ,  $n = 8$ , respectively). Particularly, at  
39  
40 315 I condition, the highest S and N values were recorded in spring and summer  
41  
42 316 while H' values were relatively constant between seasons (Figure 7). Moreover,  
43  
44 317 S and N showed strong differences between autumn and winter versus spring  
45  
46 318 and summer (Tukey test  $p = 0.00$   $n = 16$ ), and were no differences between  
47  
48 319 autumn versus winter (Tukey test  $p = 0.00$ ;  $n = 18$ ). Similarly, N showed strong  
49  
50 320 differences between all the seasons (Tukey test  $p = 0.00$ ;  $n = 16$ ) except  
51  
52 321 between autumn versus winter (Tukey test  $p = 0.15$ ;  $n = 16$ ). Regard to E

322 condition, S had no significant differences among autumn, winter and spring  
323 (Tukey test  $p > 0.05$ ,  $n = 16$ ) but did between winter and summer (Tukey test  $p$   
324 = 0.029,  $n = 16$ ). Total abundance were similar between autumn versus winter  
325 (Tukey test  $p = 0.17$ ,  $n = 16$ ) and spring (Tukey test  $p = 0.06$ ,  $n = 16$ ), and in  
326 summer was significantly higher than the other season (Tukey test  $p < 0.01$ ,  $n =$   
327 16). Likewise,  $H'$  in autumn, spring and summer were similar (Tukey test  $p =$   
328 0.99,  $n = 16$ ), but in winter showed differences compared to spring and autumn  
329 (Tukey test  $p = 0.006$  and  $p = 0.016$ ;  $n = 16$ , respectively).

330

331 Overall, the macrobenthic community was functionally composed of biodiffusors  
332 (surficial biodiffusors, epifaunal biodiffusors and gallery-biodiffusors),  
333 regenerators, and upward conveyors (Table 1). Upward conveyors  
334 predominated in autumn (61%) and winter (76%). Spring showed more  
335 balanced repartition between upward conveyors and biodiffusors, and this latter  
336 finally represented 81% of the functional groups in summer (Figure 8).

337

### 338 3.3. Bioturbation

339 The depth distributions of the luminophores for the two particles range sizes  
340 (pink and green) were similar (Kruskal-Wallis test  $p > 0.05$ ;  $n = 32$ ). Although  
341 the main bioturbation activity was recorded until 2 cm depth, both tracers were  
342 found buried down to 13 to 17 cm depth within the different sediment cores and  
343 seasons (Figure 9). The shapes of the tracer's distribution were also the same  
344 whatever the tracers and seasons showing a combination between a  
345 biodiffusive-like distribution from the surface completed by the presence of  
346 tracers deeper down. Thus, all tracers (pink and green) data were pooled

40  
347 together and the gallery-diffusor model (François et al., 2002) was used to  
348 calculate the apparent bio-diffusion ( $D_b$ ) and bio-advection ( $r$ ) coefficients within  
349 each core. Like previously observed for the majority of physical, chemical, and  
350 biological parameters, whatever the season the calculated coefficients did not  
351 show differences between the sediments incubated *in situ* and *ex situ*  
352 conditions (Kruskal-Wallis test  $p > 0.05$ ;  $n = 16$ ). In I conditions, nor  $D_b$  nor  $r$   
353 showed season effect (Kruskal-Wallis test  $p = 0.5$  and one-way ANOVA  $p =$   
354  $0.05$ ;  $n = 16$ , respectively). Contrary, in E conditions, highly significant  
355 differences were found for the  $D_b$  coefficient between autumn versus spring and  
356 summer versus autumn and winter (Fisher LSD test  $p < 0.01$ ;  $n = 16$ ).  
357 Moreover, the  $r$  coefficient showed significant differences between spring  
358 versus winter (Multiple comparisons test  $p < 0.01$ ;  $n = 16$ ) (Figure 10).  
359 Particularly, the  $D_b$  highest average values were found in autumn and winter  
360 ( $1.71 \pm 0.14$  and  $1.49 \pm 0.31 \text{ cm}^2 \text{ year}^{-1}$ , respectively). Nevertheless, the results  
361 were highly variable in spring and summer. Finally, maximum values of  $r$  were  
362 recorded in spring and summer (Figure 10).

#### 363 364 **4. Discussion**

365 The seasonal composition and functioning (sediment reworking activity) of the  
366 intertidal macrobenthic community of Caleta Valdés (CV) applying an *in situ* and  
367 *ex situ* experimental protocol were evaluated. The macrofaunal invertebrates (>  
368  $0.5 \text{ mm}$ ) occupy almost every trophic level in marine ecosystems and influence  
369 the physical, chemical, and biological structure surroundings (Lenihan and  
370 Micheli, 2001). Moreover, it is recognized that soft-sediment ecosystems are  
371 driven by complex interactions between water column processes, organic

372 matter inputs and their utilization by benthic populations, and the hydrodynamic  
373 and sedimentary conditions (Barry and Dayton, 1991; Snelgrove and Butman,  
374 1994). The coastal sediments of shallow environments play a key role in  
375 nutrient recycling because they can provide even greater fluxes to the water  
376 column than those from the continent (Clavero et al., 2000; Niencheski and  
377 Jahnke, 2002). Moreover, numerous studies highlight the importance of  
378 physical processes such as the velocity and intensity currents as the main  
379 environmental factors that influence the benthic systems (Pastor de Ward,  
380 2000). These factors determine the granulometry of the sediment (Brown and  
381 McLachlan, 2010; Dauvin et al., 2004; Muniz and Pires, 2000, among others)  
382 and food availability (Brown and McLachlan, 2010; McLachlan and Dorvlo,  
383 2005), modifying the composition of the communities. In the present study, the  
384 superficial layers (0-2 cm) were enriched in fine-grained particles with a  
385 relatively high percentage of water content and organic matter, meanwhile in  
386 the sandy deeper sediment, these parameters decreased to lower and almost  
387 uniform values. Similar results were recorded in sediments from Caleta Sara  
388 (San Jorge gulf, Patagonia Argentina), applying a similar methodology  
389 (Romanut, 2019). Particularly, the benthic organisms are able to change the  
390 local geochemical conditions through the reworking of sediment particles and  
391 irrigation during feeding, excretion, and locomotion within and through different  
392 sediment layers (Flach and Heip, 1996; Kristensen and Holmer, 2001; Venturini  
393 et al., 2011). Therefore, it is not surprising that in our study the bioturbation  
394 activity was concentrated mainly in the first centimeters of the sedimentary  
395 columns, i.e., 50% of the luminophores were finally retained (Gambi et al.,  
396 1998; Gambi and Bussotti, 1999; Jorein, 1999; Venturini et al., 2011) where the

397 higher densities of macroorganisms were observed. In fact, the water-sediment  
398 interface, considered as a large sink of organic matter and oxygen, is an area of  
399 intense biological activity and remineralization (Nixon, 1981). Particularly, the  
400 combined effect of particulate and fluid transport on sediment biogeochemical  
401 processes is reflected in the vertical color transition (from brown to olive  
402 green/black) of the sediment profile (Lyle, 1983). This color transition is dictated  
403 by the change from iron (oxyhydr)oxides at the surface to black sulphidic  
404 phases at depth (Statham et al., 2017) correlating with a variety of  
405 environmental drivers (Solan et al., 2019). Moreover, depending on the  
406 biogeochemical transformations developed in this zone by the benthic  
407 communities, the sediment may be source of some nutrients and sink for others  
408 (Cabrita and Brotas, 2000).

409  
410 Macro-benthic fauna is a key element of many marine and estuarine monitoring  
411 programs but those usually do not (or cannot) take into account distribution  
412 patterns at different spatial-temporal scales (Ysebaert and Herman, 2002). In  
413 the present study, the abundance of the dominant taxa and the bioturbation  
414 activity (especially in depth) were globally higher in spring-summer ( $D_b = 1.04 \pm$   
415  $0.59 \text{ cm}^{-2} \text{ y}^{-1}$  and  $r = 12.60 \pm 3.22 \text{ y}^{-1}$ ) than in the rest of the seasons ( $D_b = 1.59$   
416  $\pm 0.26 \text{ cm}^{-2} \text{ y}^{-1}$  and  $r = 4.81 \pm 5.85 \text{ y}^{-1}$ ). The  $D_b$  and  $r$  values recorded at CV  
417 were in the range of those measured in Mediterranean Sea lagoons, the Thau  
418 lagoon, and the Carteau Cove by Duport et al. (2007) and Gilbert et al. (2015),  
419 respectively. Nevertheless, we can go no further in the comparison between  
420 sites because the sediment mixing intensity is mainly driven by population  
421 biomass (Matisoff, 1982; Reible et al., 1996), density (Duport et al., 2006;

422 Ingalls et al., 2000; Mermillod-Blondin et al., 2001; Sun et al., 1999), and  
423 interspecific variability within functional groups (François et al., 1999).  
424 Moreover, it can be modulated by environmental conditions (e.g. Gilbert et al.,  
425 2021; Hollertz and Duchêne, 2001; Maire et al., 2007; Nogaro et al., 2008;  
426 Orvain and Sauriau, 2002; Ouellette et al., 2004).

427  
428 The maximum of macrofauna abundance recorded in spring-summer in this  
429 study were similar to those found at Cerro Avanzado (Golfo Nuevo, Patagonia  
430 Argentina) which was associated with higher juvenile occurrence and primary  
431 productivity (Lizarralde et al., unpublished data). This increase could be also  
432 influenced by the closeness to the Península Valdés frontal system, which is  
433 one of the best-known tidal fronts on the northern Patagonian continental shelf  
434 (Derisio et al., 2014). These fronts are generated usually within the same water  
435 mass where the boundary between stratified (offshore) and coastal vertically  
436 mixed water is found (Sabatini and Martos, 2002). In temperate climates,  
437 seasonal thermoclines are established near the surface during late spring and  
438 summer. This structure is maintained until autumn when stratification breaks  
439 down (Acha et al., 2004; Carreto et al., 1986; Glorioso, 1987). The fronts are  
440 zones where the lateral and vertical mixes are increased producing an increase  
441 of the primary and secondary production (Mann and Lazier, 2005; Olson and  
442 Backus, 1985; Yamamoto et al., 2000). The vertical circulation not only  
443 promotes the fertilization by nutrients in the surface (Mann and Lazier, 2005)  
444 but also the sinking water with the exportation of particles and organisms to the  
445 deepest strata facilitating the persistence of big invertebrates and vertebrates  
446 benthic populations (Sournia, 1994; Turley et al., 2000). The highest

447 concentrations of *Zygochlamys patagonica* found in the region have also been  
448 related to the formation of this front (Bogazzi et al., 2005). Viñas and Ramírez  
449 (1996) have reported previously eggs and nauplii of copepods peaking in frontal  
450 waters off Península Valdés at highest chlorophyll “a” concentration zones. The  
451 importance of the fronts to the benthic communities lies not only on the high  
452 primary production but also by vertical fluxes that transport food particles to the  
453 bottom and by the weakening of the vertical stratification that allowing  
454 increasing the particulate material sink rate. This material rich in labile OM is  
455 consumed and incorporated into the benthic biomass. Particularly, all dominant  
456 taxa recorded in CV except *Axiothella* sp. were more abundant in the spring-  
457 summer period. The feeding modes are not defined specifically for *Exogone*  
458 *molesta* (Syllidae), *Cerathocephale* sp. (Nereididae), *Scoloplos* sp. (Orbiniidae),  
459 *Oligochaeta* sp. (Oligochaeta), and *Leuroleberis poulsoni* (Crustacea).  
460 Nevertheless, the members of the studied taxa generally are identifying as  
461 carnivores, filters, selective or no selective sediment feeders and scavengers,  
462 respectively. Therefore, these taxa could tend to move from the surface to the  
463 most depth zone of the sedimentary column, producing an increase of the  
464 bioturbation activity in the whole column at this period.

465  
466 From a functional point of view, the overall high activity of the spring-summer  
467 community (i.e., increased  $D_b$  and  $r$  coefficients) produced a higher deep  
468 repartition of particles than those recorded in autumn and winter, even when in  
469 summer the community was dominated by biodiffusors meanwhile in autumn  
470 and winter predominated upwards conveyors. This clearly demonstrates that  
471 the repartition of particles within sediments is strongly dependent of the

472 interactions between the different functional groups rather than the presence of  
473 a dominant group and that we cannot simply assume that the dominance of one  
474 functional group automatically produces a dominant sediment reworking  
475 process within a community. In spring-summer period in CV by example, the  
476 increase of subsurface bioturbation transport may have feed the deeper  
477 advective process resulting in a global deeper burying of surface particles by  
478 the community.

479  
480 Regarding *in situ* and *ex situ* comparing, in general terms, the community  
481 parameters profiles did not differ between the sediment incubated in field  
482 conditions versus those incubated in the laboratory. Moreover, there was a high  
483 similarity in the faunistic composition in both experiments. Consistently, there  
484 were no differences in the bioturbation activity of macrobenthic organisms for  
485 both experimental conditions. Thus allowing validation of an *ex situ*  
486 experimental protocol for macrobenthic community and functioning studies. To  
487 the best of our knowledge, there are no previous studies allowing such protocol  
488 to be validated. These results are particularly useful as a reliable alternative for  
489 ecotoxicological studies in protected environments where *in situ* addition of  
490 pollutants to the sedimentary matrix won't be feasible (see Ferrando et al.,  
491 2015, 2019; Sturla Lompré et al., 2018; Romanut, 2019; among others).

## 493 **5. Conclusions**

494 The seasonal composition and functioning of the intertidal macrobenthic  
495 community of CV were reported for the first time, contributing to the knowledge  
496 of this vulnerable ecosystem threatened by anthropogenic activities. In addition,

497 *ex situ* and *in situ* measurements demonstrated similar results, thus allowing  
498 validation of an *ex situ* experimental protocol for macrobenthic community and  
499 functioning studies. The information generated will allow assessing pollutant  
500 effects on macrobenthic communities inhabiting sediments from a natural  
501 environment without disturbing the ecosystem. In addition, these results provide  
502 a first baseline of benthic information on CV that will be helpful to monitor the  
503 effects of potential pollution in Patagonian coastal systems.
