#### Abstract

Tomato gray leaf spot was first reported in Argentina in 1990. Since then, the disease has not only increased in endemic areas, but also disseminated in other tomato-growing areas. In a survey of plants with typical symptoms of Tomato grey leaf spot disease we isolated 27 Stemphylium representatives from the two main tomato-growing areas of Argentina. Cultural features such as sporulation, conidia morphometry among others revealed high variability between isolates, which was confirmed by Inter Simple Sequence Repeat (ISSR)-PCR technique. A molecular phylogenetic analysis comprising the Internal Transcribed Spacer (ITS)

[^0][^1]and the glyceraldehyde-3-phosphate dehydrogenase ( $g p d$ ) gene partial sequences unambiguously identified all isolates as Stemphylium lycopersici. Based on disease severity on detached leaves, isolates were grouped in three categories (high, medium and low virulent). No correlation was found between phenotypic or genotypic characters and the geographical origin of the isolates.

## Introduction

Tomato (Solanum lycopersicum L.) is a major crop worldwide. Approximately 4.6 million ha are cultivated annually yielding around 163 million tons (FAO 2016). Like other crops, it is negatively affected by various pests and diseases. Currently, the estimated number of tomato diseases is about 200 (Jones et al. 2014). Among the infectious diseases, more than 76 species of fungi have been described to be pathogenic on tomato (Farr and Rossman 2016).

Tomato gray leaf spot is a disease present in most tomato-growing areas around the world with warm temperatures and high relative humidity. The etiological agents of this disease are three species of the genus Stemphylium (teleomorph: Pleospora): S. solani G.F. Weber, S. lycopersici (Enjoji) W. Yamam. (syn. S. floridanum Hannon \& G. F. Weber) and S. botryosum Wallr. f. sp. lycopersici Rotem, Y. Cohen, \& I. Wahl (Jones et al. 2014). Under the conditions described, conidia of the fungus on the leaf surface develop a germination tube that penetrates the leaf mainly through stomata but also through the periclinal cell walls of the epidermis. Then, a vesicle develops inside the substomatal cavity, from where secondary hyphae appear and colonize the entire mesophyll. The first macroscopic lesions can be seen after 36 h of infection (Bentes and Matsuoka 2005). Symptoms consist in small brownish specks, which later became grayish slightly angular lesions that are surrounded by a yellow halo. As lesions mature, the center of developing lesions dried up and become brittle. In severe attacks, yellowing occurs along the entire leaf that present a high number of spots that might coalesce in large necrotic foliar areas (Blancard 2012; Jones et al. 2014).

Traditionally, Stemphylium species have been identified based on conidial morphology. However, such characters are not only variable but are also under the influence of environmental conditions (Leach and Aragaki 1970; Hawker 2016; Snyder and Hansen 1941; Neergaard 1945; Williams 1959; Joly 1962). Molecular biology provided researchers with neutral molecular markers that are unaffected by the environment. Because of this, today the molecular phylogenetic analysis is widely used to study relationships among species, which complements studies based on morphological features. Câmara et al. (2012) stated, by a multi-locus phylogenetic analysis of the internal transcribed spacer (ITS) and the glyceraldehyde-3-
phosphate dehydrogenase ( $g p d$ ) gene partial sequences, that the genus Stemphylium is a monophyletic clade in the Pleosporaceae. This was further confirmed by Inderbitzin et al. $(2005,2009)$ by means of a multilocus approach based on the nucleotide sequences of the ITS, gpd, elongation factor $1 \alpha$ (ef- $1 \alpha$ ) and the noncoding region between the vacuolar membrane ATPase catalytic subunit A gene (vmaA) and a gene involved in vacuolar biogenesis (vpsA).

Molecular methods also have been widely used to study and analyze genetic diversity among pathogens populations. Regarding Stemphylium species, genetic variability has been studied using Random Amplified Polymorphic DNA (RAPD) (Chaisrisook et al. 1995; Mehta 2001; Nasehi et al. 2014; Sy-Ndir et al. 2015), Enterobacterial Repetitive Intergenic Consensus (ERIC) (Mehta et al. 2002), Repetitive Extragenic Palindromes (REP) (Mehta et al. 2002) and Inter Simple Sequence Repeat (ISSR) (Nasehi et al. 2014; Al-Amri et al. 2016) fingerprints. Knowledge of the structure and dynamics of pathogens populations are essential to develop a strategy to manage the disease (McDonald and Linde 2002).

In Argentina, tomato gray leaf spot was first reported in the province of Corrientes in 1990 and, since then, the disease has also been found in the main tomato growing regions in the country. Until now, the disease has been associated with S. solani and S. lycopersici, though such studies relied solely on morphological features (Colombo et al. 2001; Ramallo et al. 2005; Colombo and Obregón 2008). Furthermore, no studies regarding the genetic variability and the population structure of Stemphylium species causing gray leaf spot in Argentina have been done. Therefore, the aim of this work was to confirm the identity of the causal agent of tomato gray leaf spot disease in plant materials collected from important tomato-growing regions of Argentina by means of conventional and molecular approaches and to characterize the etiological agent based on cultural, morphological, pathogenic as well as genetic features.

## Materials and methods

Fungal samples
The work was carried out with twenty-seven Stemphylium isolates that belong to the culture collection of the Centro de Investigaciones de Fitopatología (CIDEFI), Universidad Nacional de La Plata (UNLP).

Fungal isolates were obtained from tomato (Solanum lycopersicum L.) plants collected from the main tomatogrowing areas in Argentina in 2010, 2011 and 2013 that presented typical symptoms of gray leaf spot (Table 1).

Cultural and morphological characterization
Cultural and morphological characteristics of the isolates were analyzed both in cultures grown on homemade and commercial potato dextrose agar (PDA). Homemade PDA was prepared by boiling 200 g of potatoes cv. Spunta in distilled water (11) for 1 h . Then, the filtered extract was mixed with 20 g of agar and 20 g of dextrose and it was finally boiled for an additional time ( 20 min ). Commercial PDA was prepared according to the recommendations of the manufacturer

Britania S.A. (Argentina). Each isolate was inoculated by placing a 7 mm plug from 7 -day-old cultures at the center of a plastic Petri dish, which was incubated at $25{ }^{\circ} \mathrm{C}$ in continuous darkness for 7 days. The experiment was completely at random and the number of replicates was three per isolate per culture medium. Features such as growth rate, colony color, elevation, margin, zonation, culture medium pigmentation and sporulation were examined. Colony diameter was recorded as the mean of two colony diameters at right angles for each colony. Colors were designated according to the Munsell Colour Order System as implemented in the Virtual Colour Atlas v. 2.0.0720 web application (Virtual Colour Systems LTD 2013). Sporulation capacity was estimated by adding 5 ml of $0.01 \%$ Tween 20 to the culture, which was then scrapped with the help of a spatula. The suspension obtained was homogenized by pipetting and vortexing and then, a $100 \mu \mathrm{l}$ aliquot was loaded in a modified Neubauer chamber, where spores were counted. Experiments were repeated at least three times and values were averaged. The number of conidia per square centimeter of fungal colony was estimated compared to the corresponding colony diameter. Conidia morphology was examined in lactophenol by light microscopy. Fifty mature conidia ( $\pm$ SD) were measured at $\times 100$ magnification using a calibrated ocular micrometer. Both macroscopic and microscopic observations were photo-documented. Data were subjected to a oneway Analysis of Variance (ANOVA) and means were compared by the Least Significant Difference (LSD) test ( $P=0.05$ ) using InfoStat version 20151 (Di Rienzo et al. 2015). In order to examine whether fungal growth was determined by the type of culture medium, a two-way nested ANOVA was carried out using the independent variables: culture medium and isolate.

## Virulence assessment

Virulence of Stemphylium isolates was evaluated in vitro on tomato cv. Elpida by means of a detached leaf assay. Briefly, detached leaflets from 45-days old tomato plants were placed with the adaxial side down on water-soaked filter paper inside a plastic Petri dish. Then, they were injured with a sterile tip on the abaxial side at three equidistant points where they were inoculated with a conidial suspension of $30 \mu \mathrm{l}$ of a $10^{3}$ conidia $\mathrm{ml}^{-1}$ suspension. The spore suspension was prepared as described before and filtered with sterilized cheesecloth. Since a few isolates failed to sporulate, the number of
colony forming units (CFU) was used as an estimate of the actual inoculum concentration. For these non sporulating isolates, $100 \mu \mathrm{l}$ aliquots of serial dilutions from mycelial suspensions, prepared as described above, were plated on PDA and incubated for 48 h at $25^{\circ} \mathrm{C}$. After that time, the number of CFU was determined. Controls consisted in leaflets treated with a sterilized $0.01 \%$ Tween 20 solution. Petri dishes where sealed with Parafilm to prevent water loss and were incubated for a week at $25^{\circ} \mathrm{C}$. Symptoms were examined 7 days post inoculation (dpi) and the average lesion was determined from spot infections using the image analysis software for plant disease quantification Assess 2.0 (Lamari 2002). The experiment consisted of nine replicates of one leaflet per replicate inoculated with each isolate; the experiment was repeated twice. The inoculated fungi were re-isolated in order to fulfill Koch's postulates. Data were statistically analyzed by a one-way ANOVA and differences among treatment means were contrasted by the LSD test ( $P=0.05$ ), as implemented in InfoStat version 20151 (Di Rienzo et al. 2015).

Molecular identification

## Genomic DNA extraction

Total genomic DNA was extracted from axenic cultures using the CTAB method of Bornet and Branchard (2001). The quality and quantity of genomic DNA was evaluated by electrophoresis in a $0.7 \%$ agarose gel that was stained with ethidium bromide. Gels were visualized by means of UV light and images were captured with the software GeneSnap. Genomic DNA was quantified by comparing the bands of total DNA with those of a molecular marker of known concentration with the GeneTools image analyzer (SynGene, Cambridge, UK). Extracted DNA was stored at $-70^{\circ} \mathrm{C}$ until analysis.

## PCR amplification and sequencing

Primers ITS4 and ITS5 (White et al. 1990; Table 2) were used to amplify the ITS. Primers GPDF and GPDR (Table 2), which were designed based on $g p d$ sequences of Stemphylium spp. available in the GenBank (www.ncbi.nlm.nih.gov), were used to amplify a partial sequence of the gpd gene.

Both ITS and gpd PCRs were performed in a $15 \mu \mathrm{l}$ reaction mixture containing 50 ng of template DNA,

Table 2 List of primers used to perform all the PCR amplification described in this study

| Primer | Sequence (5'-3') |
| :--- | :--- |
| AA $_{5}$ | GAG(AAG)5 |
| AN | (CAA)5 |
| BA $_{3}$ | (AC)8CT |
| GA $_{5}$ | TCA(GT)8 |
| $\mathrm{FA}_{5}$ | TAC(GA)5 |
| LA $_{5}$ | CAG(AAC)5 |
| ITS4 | AAGCTTTCCTCCGCTTATTGATATGC |

| GPDF | GACATTGTCGCCGTGAAC |
| GPDR | ACTCGACGACGTAGTAGG |

$0.3 \mu \mathrm{M}$ of each forward and reverse primer, $1.5 \mu \mathrm{l}$ 10X reaction buffer ( $500 \mathrm{mM} \mathrm{KCl} ; 100 \mathrm{mM}$ Tris- HCl , pH 9.0 a $25^{\circ} \mathrm{C}$; $1 \%$ Tween 20), $1.5 \mathrm{mM} \mathrm{MgCl}_{2}, 0.2 \mathrm{mM}$ dNTPs and 1 unit of Taq polymerase (all Inbio Highway®, Buenos Aires, Argentina). To amplify the ITS fragment the thermocycler was programed as follows: 5 min at $94^{\circ} \mathrm{C}$ followed by 33 cycles of 1 min at $94^{\circ} \mathrm{C}$, 45 s at $56^{\circ} \mathrm{C}$ and 1 min at $72^{\circ} \mathrm{C}$, followed by a final extension step of $72^{\circ} \mathrm{C}$ for 5 min . On the other hand, the fragment encoding the $g p d$ was amplified by the following parameters: 5 min at $94^{\circ} \mathrm{C}$ followed by 30 cycles of 30 s at $94^{\circ} \mathrm{C}, 30 \mathrm{~s}$ at $56^{\circ} \mathrm{C}$, and 30 s at $72^{\circ} \mathrm{C}$ and a final extension that consisted in 5 min at $72^{\circ} \mathrm{C}$. Both amplification reactions were performed using a PTC-0150 MiniCycler (MJ. Research. Watertown, MA, USA). PCR products were resolved in $1 \%$ agarose gel electrophoresis stained with ethidium bromide. Gels were visualized by UV illumination, images were captured with GeneSnap and the DNA quantified with GeneTools image analyzer (SynGene). PCR products were purified by isopropanol precipitation and were sequenced at Macrogen (Seoul, Korea).

## Sequence alignment and molecular phylogenetic analysis

The taxonomic position of the isolates was assessed by performing a molecular phylogenetic analysis. The analysis included seven representatives of five genera of the order Pleosporales (Alternaria, Bipolaris, Cochliobolus, Pyrenophora and Setosphaeria) that were chosen as outgroup and 23 representatives of the genus Stemphylium were included in the analysis.

Both ITS and gpd partial sequences were obtained from GenBank (www.ncbi.nlm.nih.gov; Table 3). Sequences were aligned with MEGA 5.10 (Tamura et al. 2011) using the default parameters of the ClustalW algorithm (gap opening penalty 15 , gap extension penalty 6.66 ). The alignments were visually checked and manually optimized. Phylogenetic analysis was performed under both Maximum-parsimony (MP) and Maximumlikelihood (ML) criteria. Previously, the partition homogeneity test (PHT) (Farris et al. 1994) was performed in order to determine whether the two loci could be concatenated into a single dataset. PHT was run in

PAUP* (Phylogenetic Analysis Using Parsimony) 4.0 b10 software (Swofford 2002) using the same parameters described below for MP analysis. MP based phylogenetic analysis was performed using PAUP* with the heuristic search option with tree bisection reconnection (TBR) branch swapping and 1000 random sequence additions. Characters were treated as unweighed and gaps were treated as missing data. Due to the excessive computational time required to conduct a heuristic MP search, the number of saved trees was limited to 100 with scores of 1 or above for each random-addition-sequence replicate. Clade stability was assessed via 1000 bootstrap

Table 3 Additional strains used in the phylogenetic analysis

[^3]replications using the heuristic search options described above. As for the ML analysis, best-fit models of nucleotide substitution were assessed with jModelTest 2 (Darriba et al. 2012) software by using Akaike Information Criterion (AIC; Akaike 1974). Parameters of the chosen models were used in PhyML 3.1 software (Guindon and Gascuel 2003) to find the mostlikelihood trees, whose branch support were estimated via 1000 bootstrap replicates.

## Genetic diversity analysis

Diversity among all the isolates was analyzed by ISSRPCR procedure (Bornet and Branchard 2001). Six micro-satellite primers were selected based on the number of polymorphic bands amplified and reproducibility of the reaction $\left(\mathrm{AA}_{5}, \mathrm{AN}, \mathrm{BA}_{3}, \mathrm{GA}_{5}, \mathrm{FA}_{5}\right.$ and $\mathrm{LA}_{5}$, Table 2). PCR amplifications were carried out in a $25 \mu \mathrm{l}$ volume containing 12 ng of template DNA, $1 \mu \mathrm{M}$ of primer, $2.5 \mu \mathrm{l} 10 \mathrm{X}$ reaction buffer $(500 \mathrm{mM} \mathrm{KCl}$; 100 mM Tris- $\mathrm{HCl}, \mathrm{pH} 9.0$ a $25^{\circ} \mathrm{C}$; $1 \%$ Tween 20), $2.5 \mathrm{mM} \mathrm{MgCl}_{2}, 0.2 \mathrm{mM} \mathrm{dNTPs}$ and 1.25 units of Taq polymerase (all Inbio Highway ${ }^{\circledR}$, Buenos Aires, Argentina). Amplifications were done using a PTC-0150 MiniCycler (MJ. Research. Watertown, MA, USA) thermocycler programmed as follows: an initial denaturation step at $94^{\circ} \mathrm{C}$ for 7 min , followed by 33 cycles of $94^{\circ} \mathrm{C}$ for $1 \mathrm{~min}, 48^{\circ} \mathrm{C}$ (primers $\mathrm{AA}_{5}$, AN and $\mathrm{BA}_{3}$ and $\mathrm{GA}_{5}$ ) or $53{ }^{\circ} \mathrm{C}$ (primers $\mathrm{FA}_{5}$ and $\mathrm{LA}_{5}$ ) for 75 s and $72{ }^{\circ} \mathrm{C}$ for 4 min , at the end all reactions had a final extension of $72{ }^{\circ} \mathrm{C}$ for 7 min . ISSR-PCR products were resolved in $1.5 \%$ agarose gels stained with ethidium bromide. Gels were run at 70 V , until the dye front gets close to the bottom of them. Gels were then exposed to UV illumination and images were captured with GeneSnap software (SynGene).

The ISSR-PCR banding patterns obtained from stable amplified bands were arranged into a binary data matrix, scoring 0 for the absence and 1 for the presence of band. A multivariate analysis was carried out using Past3 software (https://folk.uio.no/ohammer/past/). The Dice similarity index was used to create a similarity matrix from which a dendrogram was derived using the Unweighed Pair Group Method with Arithmetic Mean (UPGMA) algorithm. In order to measure the genetic variation within and among geographical distinct Stemphylium populations, an Analysis of Molecular Variance (AMOVA) was performed in Arlequin 3.5.2.2 (Excoffier et al. 2005).

## Results

All the isolates obtained from diseased tomato tissue with typical symptoms of tomato gray leaf spot were initially identified as Stemphylium lycopersici by means of the ITS partial sequence. Therefore we decided to further characterize the isolates based on cultural, morphological as well as molecular features.

Cultural and morphological characterization

Cultural and morphological characters varied markedly between isolates, whether they were cultured on homemade or commercial PDA. Mean colony diameter ranged from $25.00 \pm 1.00 \mathrm{~mm}$ (CIDEFI-212) to $79.33 \pm 2.30 \mathrm{~mm}$ (CIDEFI-230) after 7 days of incubation at $25{ }^{\circ} \mathrm{C}$. Isolates CIDEFI-200, CIDEFI-201, CIDEFI-210, CIDEFI-212 and CIDEFI-231 were among the slowest growing isolates (Fig. 1). Variations in colony diameter have also been found within the same isolate, as was the case of isolate CIDEFI-229 which reached a mean colony diameter of 70.33 mm on commercial PDA but grew only up to 25 mm when cultured on homemade PDA (Figs. 1 and 2). Differences between and within isolates have also been observed in other cultural characters such as colony color, texture, elevation, margin and the existence of zonation and its patterns. For instance, when isolate CIDEFI-203 was grown on homemade PDA it showed flat cottony colonies that were white, moderate olive green and brilliant yellow green in color and undulate margins that additionally presented a concentric zonation. Under the same conditions, the same isolate cultured on commercial PDA developed cottony colonies that were white, vivid yellow and pale orange yellow in color, with regular margins and the absence of zonation (Fig. 2).

None of the isolates sporulated on commercial PDA. However, on homemade PDA sporulation occurred though it varied markedly. On one extreme, isolates CIDEFI-201, CIDEFI-210, CIDEFI-212 and CIDEFI231 did not sporulate. On the other extreme, isolate CIDEFI-218 produced 63,057 spores per square centimeter of aerial mycelia. The rest of the isolates differed in their capacity between these two extremes. It is important to mention that non sporulating isolates CIDEFI201, CIDEFI-210, CIDEFI-212 and CIDEFI-231 shared cultural features such as the diffusion a vivid greenish yellow color that changed to a deep red one as the culture grew older. Cultural characteristics of all isolates

Fig 1 Mean colony diameter of Stemphylium isolates grown on homemade or commercial PDA medium after 7 day of incubation at $25^{\circ} \mathrm{C}$ in continuous darkness. Values are means of three independent biological replicates and error bars represents the standard deviation
are described in Table 4 and pictures are exhibited in Electronic supplementary material 1 (ESM_1).

Conidiophores were light brown in color, septated and $3.6 \mu \mathrm{~m}$ wide with distinctly swollen apical cells that were $7.2 \mu \mathrm{~m}$ wide. Conidial shape was oblong, rounded or pointed at the apex, with a prominent dark brown scar at the rounded base. They were light brown and cell wall ornamentation was verruculose. Marked variations have also been observed in conidia dimensions and length to width (L:W) ratios, which varied from 2.2 (CIDEFI230) to 3.1 (CIDEFI-206, CIDEFI-219). Morphological characteristics of conidia of all the isolates that
sporulated in vitro are detailed in Table 5 and some examples are exhibited in Electronic supplementary material 2 (ESM_2).

## Virulence

Whether inoculated as a spore or mycelia suspensions all isolates provoked disease on tomato cv. Elpida that developed typical symptoms of tomato gray leaf spot. Non sporulating isolates CIDEFI-201, CIDEFI-210, CIDEFI-212 and CIDEFI-231 were inoculated as a mycelial suspension of $4.10^{3} \mathrm{CFU} . \mathrm{ml}^{-1}$,

Fig 2 Variation in cultural characteristics of Stemphylium isolates grown on homemade or commercial PDA. Pictures were taken from 7-day old cultures grown on PDA at $25^{\circ} \mathrm{C}$ in continuous darkness

[^4]$1.10^{3}$ CFU.ml ${ }^{-1}, 1.10^{3}$ CFU. $\mathrm{ml}^{-1}$ and $7.10^{3}$ CFU. $\mathrm{ml}^{-1}$, respectively. Virulence assays confirmed that all isolates were pathogenic on detached tomato leaves. Symptoms developed 2 dpi and thereafter lesions expanded through the leaflet. Control leaflets treated with sterilized $0.01 \%$ Tween 20 solution remained healthy. We successfully re-isolated all the isolates from diseased leaflets fulfilling in this way Koch's postulates.

Isolates differed in the quantity of disease they provoke, which was shown by the level of severity of inoculated leaflets. Based on this, isolates can be roughly classified as highly virulent ones, like isolates CIDEFI-207, CIDEFI-215, CIDEFI-211, CIDEFI-228, CIDEFI-202, CIDEFI-216, CIDEFI-229, CIDEFI-220, CIDEFI-214, CIDEFI-230 and CIDEFI-226. The leaflet areas affected by these isolates ranged between
$6.60 \pm 1.05 \mathrm{~cm}^{2}$ and $3.75 \pm 1.11 \mathrm{~cm}^{2}$. Isolates CIDEFI208, CIDEFI-225 and CIDEFI-227 seemed to be medium virulence and affected a leaflet area between $2.31 \pm 1.00 \mathrm{~cm}^{2}$ and $1.77 \pm 0.94 \mathrm{~cm}^{2}$. Finally the less virulent isolates were CIDEFI-231, CIDEFI-203, CIDEFI-204, CIDEFI-219, CIDEFI-205, CIDEFI-218, CIDEFI-201, CIDEFI-200, CIDEFI-213, CIDEFI-210, CIDEFI-217, CIDEFI-212 and CIDEFI-206, which affected an area smaller than $1,07 \pm 0,35 \mathrm{~cm}^{2}$ (Table 6 and Fig. 3).

[^5]Molecular identification

While the ITS sequence of all Stemphylium isolates was 579 bp long, the $g p d$ partial sequence was 322 bp long. Regarding the latter, isolates presented gpd sequences that differed only in base number 70, having either a $G$ or an A. This base is located in the third intron of the full-length gpd gene sequence (Locus tag: TW65_04473; Protein accession number KNG48731). This difference was used to divide isolates within two groups: Group-G and Group-A. The first was composed of isolates with a G: CIDEFI-201, CIDEFI-203, CIDEFI-214, CIDEFI-216, CIDEFI-218, CIDEFI-227 and CIDEFI-229. Group-A was integrated by isolates with an A in this position: CIDEFI-200, CIDEFI-202, CIDEFI-204, CIDEFI-205, CIDEFI-206, CIDEFI-207, CIDEFI-208, CIDEFI-210, CIDEFI-211, CIDEFI-212, CIDEFI-213, CIDEFI-215, CIDEFI-217, CIDEFI-219, CIDEFI-220, CIDEFI-225, CIDEFI-226, CIDEFI-228 and CIDEFI-230. All the ITS and gpd sequences were deposited in the DDBJ/EMBL/GenBank under the accession numbers presented in Table 7.

In order to make the analysis simpler but still informative, only an isolate of each of the two groups of organisms with the gpd was included in the phylogenetic analysis. CIDEFI-216 was selected as representative of Group-G and CIDEFI217 was chosen of Group-A. Sequence alignment of the ITS and $g p d$ sequences of the isolates and related taxa resulted in data sets of 521 and 294 bp long, respectively. The PHT of the combined ITS and $g p d$ aligned sequences gave a $p$-value of 0.577000 , thus both DNA sequences were concatenated into a single data set. ITS-gpd sequence data matrix contained a total of 815 characters, of which 504 were constant, 70 parsimony-uninformative and 241 parsimony-informative.

The most-parsimonious tree obtained from the ITSgpd analysis had a tree length of 648 steps, a consistency index of 0.7577 , a retention index of 0.7773 and a rescaled consistency index of 0.5890 (ESM_3). Regarding the ML approach, jModelTest selected HKY + I + G as the best-fit nucleotide substitution model from among 88 competing models for the ITS-gpd data ( $-\ln$ $\mathrm{L}=4055.5102$; base freq: $\mathrm{A}=0.2333, \mathrm{C}=0.2812$, $\mathrm{G}=0.2177, T=0.2678$; transition/transversion rates $=1.4080$; gamma shape $=2.5790$ ). When the selected molecular evolution model was incorporated into the phylogenetic analysis under ML criteria in

Fig 3 In vitro virulence of Stemphylium isolates against tomato cv. Elpida evaluated by the detached leaf assay. Symptoms (a) and necrotic area (b) of tomato detached leaflets 7 dpi with conidial/mycelial suspensions of Stemphylium isolates. Control leaflets were treated with a sterile $0.01 \%$ Triton X-100 solution. Values are means of nine independent biological replicates and error bars represents the standard deviation. Means followed by a letter in common are not significantly different according to LSD test at $P \leq 0.05$. The affected area was determined using the image analysis software for plant disease quantification Assess 2.0 (Lamari 2002)

PhyML, a single ITS-gpd tree was recovered (-ln $\mathrm{L}=-4113.82741$; Fig. 4). Both approaches ML and MP resulted in a well-supported monophyletic Stemphylium clade. CIDEFI-216 and CIDEFI-217 isolates were placed in the same clade together with S. lycopersici and S. xanthosomatis with bootstrap values of $97 \%$ and $91 \%$ for the MP and ML approach, respectively. Inside these clades, isolates CIDEFI-216 was closely related to $S$. xanthosomatis and CIDEFI217 to S. lycopersici.

Genetic diversity analysis
The 6 ISSR primers selected amplified 52 clear and reproducible bands that ranged from 250 bp to 2500 bp and were used to assess genetic diversity. Among them, 27 amplicons were recorded as
polymorphic ( $52 \%$ ). We built a dendrogram using the UPGMA algorithm and Dice coefficient based on the ISSR data. All the isolates of Stemphylium were clustered in two groups at a similarity coefficient of 0.83 (Fig. 5). At this level of similarity, it could be seen that CIDEFI-230 and CIDEFI-231 isolates, which had the same origin (Table 1), were separately clustered from the rest thought at a high level of similarity. At a higher similarity level of 0.88 , the remaining isolates were subdivided in two groups. It is important to point out that there was no clear relationship between these clusters and the morphological characteristics or the geographical origin of the isolates. In fact, the AMOVA stated that $95.94 \%$ of the variation was the result of differences within geographically defined populations, while only $4.96 \%$ of the variation was attributed to differences between them.

## Discussion

The incidence of tomato gray leaf spot disease over the major tomato-growing regions of Argentina has increased considerably during the last three years. Although the disease is particularly important in Northern Argentina, it has recently been observed in southern Argentina as well as drier areas such as Mendoza. It appears that tomato gray leaf spot is spreading south, which might be related to changes in temperature and precipitation that most probably occurred due to global warming.

In Argentina, the etiological agents of tomato gray leaf spot were identified as two different species of Stemphylium. While Colombo et al. (2001) identified S. solani and S. lycopersici in diseased tomatoes growing in Corrientes province, Ramallo et al. (2005) identified S. solani in diseased greenhouse tomatoes growing in Tucumán. Both reports based their identification only on morphological characters. Even though diagnosis of Stemphylium species has been traditionally relied on morphological traits, the intrinsic variability of morphological characteristics within the genus raises some questions regarding the identification of the causative agent of the disease. Because of this we made a preliminary identification based solely on the ITS sequence, which confirmed that all of them belong to the genus Stemphylium.

Cultural characteristics as well as morphology of conidia have been used to define fungal species. Cultural characteristics of fungal isolates on PDA were typical of those described for members of the genus Stemphylium (Ellis 1971) though considerable levels of diversity were observed. In addition to this, we also found that certain characters of the isolates varied whether they were cultured on homemade or commercial PDA, which not only led to changes in their growth rate and pigmentation, but also in their sporulation capacity. While isolates exhibited a wide range of sporulation capacity on homemade PDA, no sporulation was observed on commercial PDA cultures. Thus, the differences observed between the two culture media used could be due to their chemical composition. It seems that sporulation is a demanding process that requires additional nutritional factors that are not provided in commercial PDA. Griffith et al. (2007) demonstrated that management of the potato crop used as source to elaborate the PDA medium plays a critical role in the quality of the resultant culture medium. Potatoes deficient in copper led to a reduction in pigmentation of various fungal cultures, and in some cases, the number of conidia also was affected. Malca and Ullstrup (1962) found that lactose was the best carbon source for the enhancement of sporulation in the Pleosporales fungus Bipolaris zeicola (previously named Helminthosporium carbonum) and Exserohilum turcicum (previously named Helminthosporium turcicum). More recently, Zhu et al. (2008) found that sporulation, unlike mycelial growth, in Aschersonia aleyrodis was affected by the content of lactose, vitamin $\mathrm{B} 1, \mathrm{Fe}^{2+}$ and

Fig 4 Maximum likelihood tree of Stemphylium/Pleospora inferred from the concatenated ITS-gpd data set. Sequences of seven representatives of five genera of the order Pleosporales (Alternaria, Bipolaris, Cochliobolus, Pyrenophora and Setosphaeria) were chosen as outgroups. Sequences generated in
this study are in bold type letter. Numbers at the nodes represent bootstrap support values as a percentage of 1000 replicates. The scale bar represents the average number of nucleotide substitutions per site
isolates is a demanding process that is variable among isolates suggesting this that they differ quite significantly in their metabolic capacity.

Fig 5 Dendrogram generated by UPGMA cluster analysis using the Dice similarity coefficient based on the ISSR fingerprint of Stemphylium lycopersici isolates

Although conidial shape, color and ornamentation were the same for the 27 isolates, some variation in their dimensions were observed, like the numbers of transverse septa and average $\mathrm{L}: \mathrm{W}$ ratio, with the latter ranging from 2.2 to 3.1. Based on the earliest descriptions of spore morphology for Stemphylium species associated with gray leaf spot, we found that while some of our isolates fit closely to the $S$. solani phenotype, because of the shorter length, width and $\mathrm{L}: \mathrm{W}$ ratio of the conidia, others presented morphological characteristics typical of S. lycopersici, since they produce bigger spores with L:W ratios equal or higher than 3 (Weber 1930; Hannon and Weber 1955; Ellis 1971; Ellis and Gibson 1975a, b). However, Kim et al. (2004), Kwon et al. (2007), Nishi et al. (2009), Tomioka and Sato (2011), Hong et al. (2012), Kurose et al. (2014), and Nasehi et al. (2015) described isolates of S. lycopersici with conidia with L:W ratios lower than 3. Although spore morphology has been traditionally used as a diagnostic tool to delimitate species of Stemphylium, this feature is under the influence of environmental factors. Leach and Aragaki (1970) showed that differences in temperature of culture incubation led to changes in conidia morphology of S. lycopersici. Furthermore, Tomioka et al. (1997); Tomioka and Sato 2011, Hong et al. (2012) and Nasehi et al. (2015) found that the dimension and L:W ratio of $S$. lycopersici conidia on leaf lesions were different from those grown on culture medium. In fact, previous reports showed that cultural as well as morphological characteristics are unreliable tools to be used to differentiate $S$. lycopersici from $S$. solani (Hong et al. 2012; Nasehi et al. 2015). It is evident that morphological characters should be supported with molecular data in order to precisely classify and determine the organism identity.

DNA markers are reliable neutral tools to evaluate genetic diversity and sequences of conserved genes to confirm the identity of fungi. The multi-locus phylogenetic analysis of the ITS-gpd partial sequences clustered all isolates in a clade together with S. lycopersici and S. xanthosomatis with highly significant bootstrap values both in MP and ML analysis, showing that they are distinct to $S$. solani. Only two gpd sequences were found within the 27 isolates. Therefore, we included in the phylogenetic analysis isolates CIDEFI-216 and CIDEFI-217 that represent both sequences that were clustered within the $S$. xanthosomatis and S. lycopersici sub-clades, respectively. Both S. lycopersici and S. xanthosomatis share morphological
characteristics and had nearly identical ITS and gpd sequences. Although additional taxonomical studies are needed, several authors agreed that S. xanthosomatis may be a synonym of S. lycopersici with intra-specific variation (Câmara et al. 2002; Hong et al. 2012). Our results provide additional support to this hypothesis.

Virulence is one of the most important characteristic of pathogenic Stemphylium species. Virulence of Stemphylium isolates on tomato cv. Elpida detached leaves varied considerably, which was unrelated with the tomato cultivar from where isolates were collected and the geographical place of origin of the isolates. We found that an inoculum concentration of $10^{3}$ conidia $\mathrm{ml}^{-1}$ was enough to provoke disease symptoms on detached tomatoes leaflets. Moreover, mycelial fragments at a concentration of the same order of magnitude were pathogenic on detached leaves, although apparently less virulent. Isolates CIDEFI-201, CIDEFI-210, CIDEFI-212 and CIDEFI-231, which were unable to sporulate on PDA were less virulent than spore producing isolates, since they affected a leaf area smaller than $1.07 \pm 0.35 \mathrm{~cm}^{2}$. Interestingly, these isolates shared nearly identical cultural features like a vivid greenish yellow and a deep red pigment that diffuse into the culture medium.

Satellite as well as micro-satellite DNA sequences within fungal genomes are useful tools to evaluate diversity. There are several different methods to evaluate diversity such as RAPD, ERIC, REP and ISSR-PCR. However, we decided to use ISSR-PCR due to its speed, reliability, simplicity, cost-effectiveness as well as the fact that it does not require previous knowledge of the genome sequence. Genetic variability based on the ISSR-PCR fingerprint distinguished 18 genotypes, among the 27 S. lycopersici isolates. Still, the level of similarity between accessions was high and there was no relation between the genetic clusters and the phenotypic characteristics, virulence, host identity and geographical origin of the isolates, except for the cluster formed by isolate CIDEFI-230 and CIDEFI-231. In view of these results, we found likely that the fungal pathogen has been introduced to the tomato-growing areas by few inoculum sources and it was subsequently spread by moving infected plant material from one place to another. Additionally, it is also evident that the fungus is also undergoing a process of genetic variation, as can be seen in the number of genotypes found. The latter aspect should be a cause for concern as it could be led to the
emergence of fungicide-resistant isolates or new races that are hazards for the existing resistant tomato cultivars.

This work included morphological as well as molecular characterization of pathogens isolated from tomato plants with typical symptoms of gray leaf spot, suggesting that $S$. lycopersici is the causal agent of this disease in the major tomato-growing areas of Argentina. The morphological, pathogenic and genetic variability exhibited by the 27 isolates studied suggest that the pathogen is under a rapid evolving process, which is of concern when developing phytosanitary programs. In order to perform an integral research framework of the tomato gray leaf spot pathosystem we have recently sequenced the genome of $S$. lycopersici (Franco et al. 2015). Since the tomato genome is also publicly available (Tomato Genome Consortium 2012), the availability of both genome sequences and additional experimental studies may lead to the development of more efficient strategies of control of the disease.
