36 Abstract:

37  
38 The entomopathogenic fungus *Pandora neoaphidis* is a recognized pathogen of aphids,  
39  
40 causes natural epizootics in aphid populations, and interacts and competes with aphid  
41  
42 predators and parasitoids. Survival of entomophthoralean fungi in periods of unsuitable  
43  
44 weather conditions or lack of appropriate host insects is accomplished mainly by thick-  
45  
46 walled resting spores (zygospores or azygospores). However, resting spores are not  
47  
48 known for some entomophthoralean species such as *P. neoaphidis*. Several hypotheses  
49  
50 of *P. neoaphidis* winter survival can be found in the literature but so far these  
51  
52 hypotheses do not include the presence of resting spores. Resting spores were found in  
53  
54 an aphid population where *P. neoaphidis* was the only entomophthoralean fungus  
55

1 observed during surveys conducted in organic horticultural crops in greenhouses and  
2 open fields in Buenos Aires province, Argentina. This study sought to use molecular  
3 methods to confirm that these resting spores were, in fact, those of *P. neoaphidis* while  
4 further documenting and characterizing these resting spores that were produced *in vivo*  
5 in aphid hosts. The double-walled resting spores were characterized using light and  
6 transmission electron microscopy. The Argentinean resting spores clustered together  
7 with *P. neoaphidis* isolates with bootstrap values above 98 percent in the SSU rRNA  
8 sequence analysis and with bootstrap values above 99 percent the ITS II region  
9 sequence analysis. This study is the first gene-based confirmation from either infected  
10 hosts or cultures that *P. neoaphidis* is able to produce resting spores.

1 The entomopathogenic fungus *Pandora neoaphidis* (Remaudière & Hennebert) Humber  
2 (Entomophthoromycotina: Entomophthorales), is a recognized pathogen of aphids  
3 (Hemiptera: Aphididae). This fungus has a world-wide distribution, and is well known  
4 from Europe, Asia, Africa, South America and Australia (Glare and Milner 1991;  
5 Wilding and Brady 1984; Hatting et al. 2000; Scorsetti et al. 2007). *P. neoaphidis* is  
6 aphid-specific, causes natural epizootics in aphid populations and interacts and  
7 competes with aphid predators and parasitoids (Baverstock et al. 2008a). Recently it has  
8 been demonstrated that *P. neoaphidis* causes natural epizootics in different seasons at  
9 different temperatures in South America and causes host mortality up to 56.6%, thus  
10 confirming the capacity of this fungus to be an effective biological control agent  
11 (Scorsetti et al. 2010).

27  
28 Survival of entomophthoralean fungi in periods of unsuitable weather  
29 conditions or lack of appropriate host insects is accomplished mainly by thick-walled  
30 resting spores (zygospores or azygospores). However, resting spores are not known for  
31 all entomophthoralean species. Most species that are only rarely collected and poorly  
32 known probably do, in fact, form resting spores as often and in the same manner as their  
33 better known relatives, but their resting spores remain undetected from their few known  
34 specimens (Nielsen et al. 2007). However, for so common, widespread, and much  
35 studied a species as *P. neoaphidis*, the absence of information about resting spores  
36 cannot be dismissed as either accidental or artifactual. It has long been believed that  
37 resting spore production by *P. neoaphidis* either does not happen or must be  
38 extraordinarily rare.

65  
*neoaphidis*. One is that the fungus survives by continued infection of anholocyclic  
populations of aphids. This possibility is supported by the fact that the fungus is capable

1 of infecting aphids at temperatures as low as 5°C (Wilding 1970). Baverstock et al.  
2 (2008b) have suggested that *P. neoaphidis* could remain active throughout the year  
3 through a combination of continuous infection and as inoculum deposited on the soil.  
4 There is evidence reported about the capability of *P. neoaphidis* to survive for long  
5 periods outside the host in soil as conidia or as hyphal bodies (Feng et al. 1992).  
6 Schofield et al. (1995) showed that conidia remained infective for up to 32 days after  
7 incubation at 5°C in 85% RH. Nielsen et al. (2003) suggested that *P. neoaphidis* may  
8 overwinter in the soil as “loricoconidia” (resistant structures formed by the marked  
9 thickening of a conidial wall; although they may function in a manner similar to resting  
10 spores, the morphological and developmental differences between these spore types are  
11 discussed below).

12 In populations of aphids otherwise demonstrated sporulating infections of  
13 *P. neoaphidis*, Scorsetti et al. (2007) noted and illustrated a few resting spore-like  
14 structures from Argentinean aphid cadavers collected in the autumn (June 2003 and  
15 May 2004) but the taxonomic identification of these resting spores could not be  
16 confirmed by molecular or morphological techniques. The linkage between  
17 entomophthoralean resting spores and their conidial forms is not always straightforward  
18 but congruence of sequences for several genes from both resting spores and conidial  
19 states effectively confirm the linkages of resting spores with the corresponding conidial  
20 states that are the basis for entomophthoralean taxonomy. Thomsen and Jensen (2002)  
21 used a nested PCR techniques to link resting spores with the *Entomophthora* conidial  
22 stages affecting the same host species of flies and thus demonstrated that several  
23 differing genotypes within the *E. muscae* species complex could each complete their  
24 entire life cycle in a single dipteran host species. Comparing sequences of the ribosomal  
25 repeat (SSU and ITS) is however a stronger method that also allows blast search against

2 Genbank.  
3

4 The objective of this study was to document the morphology of resting  
5 spores found in field-infected aphids where only *P. neoaphidis* infection was found in  
6 the aphid population and to use sequences of the ribosomal repeat (SSU and ITS) to  
7 confirm the *P. neoaphidis* identity of these resting spores.

## 14 Materials and Methods

### 15 Field survey

16 Surveys were conducted in organic horticultural crops in greenhouses and open fields in  
17 Buenos Aires province, Argentina, according to Scorsetti et al. (2007). Sampling was  
18 performed weekly from April 2007 to April 2008. The climatic conditions in this region  
19 are temperate with average temperature of ca. 18°C.  
20  
21

22 Lettuce (*Lactuca sativa* L.) was the main crop that was sampled, but  
23 aphids were also collected from fields of tomato (*Lycopersicon esculentum* Mill.),  
24 cabbage (*Brassica oleracea* L.), pepper (*Capsicum annuum* L.), eggplant (*Solanum*  
25 *melongena* L.), Swiss chard (*Beta vulgaris* var. *cicla* L.), and artichoke (*Cynara*  
26 *scolymus* L.).

### 34 Laboratory

35 Field-collected dead and living aphids were placed individually in plastic cups with lids  
36 (150 cm<sup>3</sup>). Dead aphids with or without external signs of mycosis were collected with  
37 the piece of plant substrate onto which they were attached by rhizoids, and were then

64  
65

1 placed individually into sterilized plastic containers (100 cm<sup>3</sup>) and transported to the  
2 laboratory for analysis of fungal infection.  
3

4 Dead aphids showing no external signs of mycoses were put in 60 mm  
5 Petri dishes with a moistened filter paper and maintained at 20° C for 24–72 h to allow  
6 the complete development of any fungi present in them. Healthy aphids were preserved  
7 in 70% ethanol as reference specimens for further taxonomic identification.  
8  
9

10 The pathogen affecting the aphids collected during these studies was  
11 confirmed to be *Pandora neoaphidis* by using standard taxonomic literature (Keller  
12 1987, 1991; Humber 1989; Balazy 1993).  
13

14 *P. neoaphidis*-infected aphids were stored at 4 °C for one month in 60 mm  
15 Petri dishes with a moistened filter paper, and then examined using a stereoscopic  
16 microscope every 72 hours for the possible development of environmentally resistant  
17 resting structures.  
18  
19

20 Microscopic characteristics were described from aphids with resting  
21 spores mounted in aceto-orcein (1% w/v) and observed on an Olympus CH3  
22 microscope. Fungal preparations were observed on an Olympus BX51 microscope and  
23 photographed using an Olympus DP71 camera.  
24  
25

26 Semi-permanent slides were made according to Humber (1997) and  
27 deposited as herbarium material in the Mycological Collection of the Institute of Botany  
28 Carlos Spegazzini (LPSC, La Plata, Buenos Aires, Argentina).  
29  
30

31 The aphids containing resting spores were preserved individually in  
32 Eppendorf microcentrifuge tubes containing 48% ethanol and kept at 4°C in darkness  
33 until either extraction of the DNA or fixation for transmission electron microscopy.  
34

1 For transmission electron microscopy, thick-walled spores from a mechanically  
2 disrupted infected aphid were fixed for 2 hours in 3% glutaraldehyde, post-fixed for 1  
3 hour in 1% osmium tetroxide, dehydrated in a graded series of 30-100 % ethanol,  
4 cleared in propylene oxide, and embedded in Epon 812. Thin (60 nm) sections were cut  
5 with a diamond knife, stained with uranyl acetate and lead citrate, and examined using a  
6 JEM 1200EX II (Jeol) transmission electron microscope.

### 17 DNA extraction, PCR amplification, and sequencing

18 Two of the infected aphids bearing resting spores were used for the molecular  
19 identification. Each of the aphids was transferred into new Eppendorf microcentrifuge  
20 tubes, the ethanol was allowed to evaporate, and the cadavers were mechanically  
21 disrupted with a sterile plastic pistil in 100  $\mu$ l MiliQ water. The samples were washed  
22 twice by centrifugation for 2 min at 10,000 x G. The supernatants were discarded and  
23 100  $\mu$ l MilliQ water was added to each preparation. Five  $\mu$ l of the washed spore  
24 suspension was added to a glass slides coated with Gel Slick Solution (BioWhittaker  
25 Molecular Application BMA; Rockland, ME, USA), and another coated slide was put  
26 on top of the spores. The resting spores were then disrupted mechanically by pressing  
27 the slides hard with the thumbs with simultaneous circular movements of the top slide.  
28 One  $\mu$ l of the crushed spores was used as template for the PCR amplification. The  
29 DNeasy® Plant Mini Kit (Qiagen GmbH, Hilden, Germany) was used to extract the  
30 DNA from *in vitro* cultures of *P. nouryi* ARSEF 362, *P. nouryi* ARSEF 366 and *P.*  
31 *bullata* ARSEF 116, following the manufacturer's instructions. The three *in vitro*  
32 cultures were obtained from the ARSEF the USDA-ARS Collection of  
33 Entomopathogenic Fungal Cultures and were grown in Graces liquid medium from  
34 where hyphal mass was collected and freeze dried upon DNA extraction.

Universal fungal primers nu-SSU-0021-5' and nu-SSU-1780-3' (Gargas and DePriest 1996) were used to amplify the nuclear small subunit ribosomal RNA gene (SSU rRNA) with an initial denaturation for 3 min at 94°C, followed by 35 cycles with denaturation for 1 min at 94°C, annealing for 1 min at 60°C, extension for 1.5 min at 72°C, and a final extension for 7 min at 72°C. Universal fungal primers ITS1 and ITS4 (White et al., 1990) were used to amplify the Internal Transcribed Spacer (ITS) regions of ribosomal DNA with an initial denaturation for 3 min at 94°C, followed by 35 cycles with denaturation for 1 min at 94°C, annealing for 1 min at 55°C, extension for 1.5 min at 72°C, and a final extension for 7 min at 72°C. Fungal universal primers were used as a positive amplification control to assure availability of DNA from the full range of entomophthoralean species studied here.

The PCR reactions were carried out in 50 µl volumes each with 200 µM of each dNTP, 1 µM of each primer, 1 x Phusion HF Buffer (with 1.5 mM MgCl<sub>2</sub>), 0.5 unit Phusion DNA polymerase (Finnzymes; Espoo, Finland) and 1 µl template (DNA extractions from *in vitro* cultures or DNA from *in vivo* material). Prior to sequencing, the PCR-products were purified with the illustra<sup>TM</sup> DNA and Gel Band Purification Kit (GE Healthcare; Buckinghamshire, UK). The purified PCR products were sent to Eurofins MWG Operon (Ebersberg, Germany) for sequencing in both directions. The following primers were used for sequencing of the SSU: nu-SSU-0021-5' and nu-SSU-1780-3' (Gargas and DePriest 1996) and nu-SSU-0553-3', nu-SSU-0573-5' and nu-SSU-1150-5' (White et al. 1990) and for the ITS we used following primers for sequencing ITS1 and ITS4 (White et al., 1990), Nu-5.8S-5' (Jensen and Eilenberg 2001) and Nu-5.8S-3' (Jensen et al. 2009).

In order to confirm the taxonomic affinity of the resting spores we blasted the sequences against the GenBank database. In addition the resting spore SSU rRNA

1 sequence was aligned with published SSU rRNA sequences from other  
2 entomophthoralean species including three new SSU rRNA sequences—one from *P.*  
3 *bullata* and two from *P. nouryi* isolates—were obtained for the current study (Table 1).  
4  
5

6  
7 The sequences were checked and aligned with *Bioedit* v7.0.8.0. Parsimony  
8 and neighbour-joining analyses with 1000 bootstrap replications to determine the  
9 support for internal branches were performed using MEGA 4 (Tamura et al. 2007). In  
10 the SSU rRNA analysis *Entomophthora muscae* and *Entomophaga aulicae* were used as  
11 outgroup taxa. In the ITS II analysis all the *Zoophthora radicans* isolates were used as  
12 outgroups.

## 24 **Results**

25  
26 Among the 562 *Pandora*-infected aphids that were studied, six cadavers included  
27 structures with thick, double-layered walls that appeared to standard entomophthoralean  
28 resting spores. These six individuals were held at 4°C for an additional six (n=4) or nine  
29 (n=2) days to allow the full development and maturation of the spores. All cadavers  
30 with the putative resting spores were collected in mid-winter (August and September  
31 2007) from *L. sativa* plants growing in open fields, and all of these hosts were identified  
32 as *Nasonovia ribisnigris* (Mosley) (Hemiptera: Aphididae).

43

44 These six aphids were preserved in 48% ethanol. Two of them were  
45 processed for transmission electron microscopy (TEM), another two were used for  
46 DNA extraction to determine the species identification by molecular analyses, and the  
47 remaining two are retained as voucher specimens deposited as herbarium material in the  
48 Mycological Collection of the Institute of Botany Carlos Spegazzini (LPSC 47460), La  
49 Plata, Buenos Aires, Argentina).

The resting spores in these aphids averaged  $31.4 \pm 2.4 \mu\text{m}$  diam (24.8–37.2  $\mu\text{m}$ ;  $n= 300$ ) (Fig. 1 a,b), and were produced both internally and externally on the surface of the aphid cadaver. The macroscopic appearance of aphids filled with these structures was dry and “sandy”. The resting spores were spherical, globose, with surface slightly covered by rounded depressions, varying from a pale yellow tint to deep amber (with the color apparently confined to the walls). The spores appeared to be mature and dormant since there was a single consolidated oil droplet filling most of the volume of individual spores (Fig. 1b).

Cross-sections of the resting spores observed with TEM show two layers of the spore wall, a thin electron-dense (dark) outer layer, and a much thicker electron-lucent (light) inner layer (Fig. 1 c,d).

We obtained a sequence of the SSU rRNA gene from resting spores of one aphid. The closest BLAST correspondences (those with 99 to 100% nucleotide identify) of the 1800 bp sequence from these resting spores were with eight different *P. neoaphidis* sequences. The resting spore SSU rRNA sequence was aligned with other published entomophthoralean SSU rRNA sequences but we only used the first 1100 positions for the sequence analyses (the SSU alignment used can be found as supplement 1) since the SSU rRNA gene was only partially sequenced for several of the other published entomophthoralean species that we wanted to include.

The SSU rRNA sequence from the Argentinean resting spores clustered together with those from conidial material of *P. neoaphidis* (Fig. 2) with bootstrap values above 98 percent and 100 percent in the NJ analysis (data not shown).

The size of the amplified ITS region varied among the different species included in this analysis from ca. 1000 to 1500 bp (Table 1). Amplicons of the resting spores from both aphids had a length of 1080 bp, as did those from all the tested *P.*

*neoaphidis* isolates. We obtained ITS sequences from the resting spores of both aphids, and these resting spore sequences were identical. When the sequences from the resting spores were blasted *P. neoaphidis* came out with 99 percent nucleotide identity with all the 18 deposited *P. neoaphidis* sequences. *P. kondoiensis* followed with only 87 percent nucleotide identity of the part that could be aligned. The variation of the whole ITS sequences within Entomophthoraceae and even within species that produce uninucleate conidia was too high for making unambiguous alignments. Most of the variation and also the ITS size differences were found in the ITS I region, and therefore only the ITS II region (including the 5.8s rRNA gene covering in all 585 positions including gaps) was used for the sequence analyses corresponding to 490–1030 bp of the GenBank sequence AF543202 of the *P. neoaphidis* isolate NW 343. Based on the SSU rRNA analysis we chose the *Zoophthora* clade as outgroup (the ITS II alignment used can be found as supplement 2).

In the sequence analyses of the ITS II region the resting spore sequences clustered with those of *P. neoaphidis* (Fig. 3) with bootstrap values above 99 percent (100 percent in the NJ analysis).

## Discussion

The major finding of this study is that the resting spores of *Pandora neoaphidis*, the most important entomophthoralean pathogen of aphids worldwide, have been found from field-infected aphids that were collected in La Plata, Argentina. Except for the report by Scorsetti et al. (2007) that is placed in its appropriate perspective by the findings reported here, no previous publication on the taxonomy or biology of this species has provided any significant information about the morphology—or even the existence—of resting spores for this nearly ubiquitous species.

1  
2 In the literature, the studies of overwintering survival by *P. neoaphidis*  
3 focused on the conidial state (Brobyn et al. 1985; Morgan 1994; Nielsen et al. 2003).  
4  
5 Despite several hypotheses about the morphological structures that might be responsible  
6  
7 for the winter survival of this fungal species, there were hints in Scorsetti et al. (2007)  
8  
9 that *P. neoaphidis* could produce resting spores in field-infected aphids, but there were  
10  
11 not enough spores in those collections to allow gene-based confirmation of their  
12  
13 identification as *P. neoaphidis*. Uziel and Kenneth (1986) suggested that a culture of *P.*  
14  
15 *neoaphidis* produced what they believed to be resting spores in completely uncontrolled  
16  
17 laboratory conditions, but the sizes of these structures (average diameter of 74.2  $\mu\text{m}$ ,  
18  
19 range 52-119  $\mu\text{m}$ ) were substantially larger than any other resting spores reported  
20  
21 within Entomophthorales, and the nature of these structures remains uncertain.  
22  
23  
24

25  
26 In the present study we never found either hyphal bodies or loricoconidia as  
27  
28 environmentally resistant structures in *P. neoaphidis*-infected aphids as had been  
29  
30 reported by other authors (Feng et al. 1992, Nielsen et al. 2003), but did find the  
31  
32 presence of spores with the thick, double-layered walls that are characteristic of all  
33  
34 entomophthoralean resting spores as the presumptive overwintering structures, and  
35  
36 these thick-walled spores were collected only during the mid-winter. Apart from the  
37  
38 molecular evidence presented here, the morpho-developmental evidence also confirms  
39  
40 that these *P. neoaphidis* spores must be resting spores. Most of these spores formed  
41  
42 inside the aphid bodies although some were superficial on the cadaver; their walls were  
43  
44 distinctly double-layered; and their shapes were spherical rather than elongated (in no  
45  
46 way similar to *P. neoaphidis* conidia). As defined by Weiser and Batko (1966),  
47  
48 loricoconidia represent a single-layered thickening of a conidial wall that necessarily  
49  
50 reflect the shapes of the conidia from which they form, and they can occur only where  
51  
52 conidia are (or were) also present. The conidia of *P. neoaphidis* form exclusively on the

1 surface of—and never inside—an infected host, and as in most entomophthoralean  
2 entomopathogens, no conidia were formed on the infected hosts where the resting  
3 spores formed.  
4  
5

6  
7 The study site in Buenos Aires province is located in the Pampeana  
8 phytogeographic region of Argentina (Cabrera and Willink 1973), and it is important to  
9 note that this site has a temperate climate with an average annual temperature of 18° C  
10 and winter temperatures generally within the range of 3–8° C. Zhou and Feng (2010)  
11 demonstrated that lower temperatures and longer daylight may result in more resting  
12 spore production by *P. nouryi* in host cohorts at a given spore concentration. The  
13 positive effect of lower temperature on the resting spore formation agrees with most  
14 previous reports on the same phenomenon for other Entomophthorales (Steinkraus and  
15 Kramer 1989, Feng et al. 1992, Pell et al. 2001). Survival structures often also require  
16 periods of cold in order to be able to germinate (Hajek, 1997). The exact requirements  
17 for dormancy and for initiation of germination and conidiation are poorly understood  
18 for almost all entomophthoraleans (Nielsen 2002), and they have remained completely  
19 unknown for *P. neoaphidis*.

39 This study of Argentinean aphids presents the first genomically verified  
40 evidence that *P. neoaphidis* is, indeed, able to produce resting spores. To learn more  
41 about the environmental (or other) conditions that allowed the production of this  
42 previously unobserved spore state should be a high priority. Progress on these issues  
43 will provide key insights about the field ecology of this fungus and the biological  
44 mechanisms controlling the initiations of epizootics of this aphid pathogen in Argentina  
45 and throughout the world. More studies are needed to locate further natural instances of  
46 these resting spores, to determine what conditions might favor the breaking of the  
47 (presumed) dormancy of fully mature spores, and whether there might be any means to

implication. *Journal of Invertebrate Pathology* **103**: 83-88.

Figure captions:

1  
2 Figure 1: Differential interference contrast micrograph (a), and phase contrast  
3 micrograph, (b) of *Pandora neoaphidis* mature resting spores, with a central oil droplet  
4 (Od) filling most of the spore's volume. Scale bar: 50  $\mu$ m. Ultrastructure of double  
5 spore wall of the resting spore, immature (c) and mature spore (d).  
6  
7  
8  
9  
10  
11  
12 Thin outer layer (w1), wide inner layer (w2), c: Cytoplasm. X30000.  
13  
14  
15

16  
17 Figure 2: Taxonomic relationships among members of Entomophthoraceae with  
18 uninucleate spores inferred from parsimonious analysis of 1080 positions of the nuclear  
19 SSU RNA gene. The tree is one out of 20 most parsimonious trees which require 562  
20 steps with a consistency index = 0.6405 and retention index = 0.8105. Bootstrap  
21 percentages from 1000 replicates are shown above each of the major branches.
