8 Running title: Germination response of forbs to fire cues

9

10 **Abstract**

11 Fire is a key ecological factor affecting plant dynamics. In the last decades, fire
12 occurrence in the Chaco region has increased noticeably, challenging the adaptive capacity of
13 plants to regenerate after a fire. Broad-leaved forb species have been much less studied than
14 woody and graminoids, although they are an important component of fire dynamics. Here we
15 analyzed the germination response to heat shock of 70°C and 110°C, smoke and their
16 combination in 10 broad-leaved herbaceous species frequently occurring in the Chaco Serrano of
17 Córdoba province, central Argentina, including five annual (*Bidens subalternans*, *Conyza*
18 *bonariensis*, *Schkuhria pinnata*, *Tagetes minuta* and *Zinnia peruviana*) and five perennial
19 species (*Borreria eryngioides*, *Sida rhombifolia*, *Solidago chilensis*, *Taraxacum officinale* and
20 *Verbena litoralis*). We also compared the response of annual vs perennial species. Six species
21 had highest germination when treated with heat and smoke combined, whereas two had lowest
22 germination under this treatment, indicating synergistic and antagonistic interaction of these
23 factors, respectively. Most of the species tolerated heat shock (i.e. germination was similar to
24 that in control treatment), whereas others had higher germination in response to heat shock,
25 especially under the moderate 70°C treatment. Germination was higher than control (i.e. no heat
26 and no smoke) after smoke treatment in four species. Perennial species showed higher average
27 germination than annuals in both heat treatments and in the control. Annual species had higher
28 average germination for all treatments involving smoke. The high variability observed at the
29 species level, and the limited number of species studied calls for precaution in interpreting and
30 extrapolating results. Nevertheless, our study shows a general positive response of both
31 perennial and annual species to fire cues, suggesting an advantage of these species for
32 colonizing post-fire environments, and being favoured under scenarios of increasingly frequent
33 low-to-medium intensity fires.

34

35 **Key words:** broad-leaved herbs, germination cues, life history strategies, post-fire
36 regeneration, seed mass

37 **Introduction**

38 Germination is one of the most significant stages in a plant's life cycle on which the
39 development of the following generation depends (Harper 1977). Seeds always aim to maximize
40 their establishment and survival (Reigosa *et al.* 2004), and therefore, physiological processes
41 and traits related to germination are key aspects of a plant's response to different disturbances.

42

43 Fire is a widely distributed ecological factor in worldwide ecosystems. It is one of the
44 main factors affecting vegetation dynamics (Bond & Keeley 2005), causing direct removal of
45 plant biomass and affecting species survival and growth, as well as the establishment of new
46 individuals from seeds, especially in fire-prone regions. As a consequence, several species have
47 developed different recruitment strategies to optimize post-fire survival. For example, in regions
48 with Mediterranean climates, where fire has been a very important evolutionary factor, seeds of
49 many species can tolerate or be stimulated by high temperatures (e.g. 120C°) or other fire-
50 related factors, such as ashes and smoke (Hanley & Lamont 2000; Keeley & Fotheringham
51 2000; Hanley *et al.* 2001; Luna *et al.* 2007; Ghebrehiwot *et al.* 2011; Zuloaga-Aguilar *et al.*
52 2011).

53

54 Heat shock influences germination by removing inhibitory waxy substances covering
55 the seed and/or scarifying seeds that have hard and impermeable covers, thereby allowing water
56 and oxygen exchange (Keeley & Bond 1997; Keeley & Fotheringham 2000; Hanley *et al.*
57 2001). Furthermore, smoke can promote germination by increasing the permeability of solutes
58 (ions and gases) in the subdermal cuticle of the seed (a semipermeable membrane), which
59 would be induced mainly by the presence of nitrogen oxides (Keeley & Fotheringham 1997).
60 The mechanism underlying this compound, however, is still unknown (Brown & Staden 1997;
61 Keeley & Fotheringham 1998).

62

63 Seed germination response to both heat and smoke depends on the duration and
64 intensity of treatments applied to seeds (Keeley *et al.* 1985; Keeley 1987; Auld & O'Connell
65 1991; Keith 1997; Plummer *et al.* 2001). Germination response can also vary depending on
66 whether these factors are applied individually or combined (Keith 1997; Gilmour *et al.* 2000;
67 Morris 2000; Kenny 2000; Tieu *et al.* 2001; Thomas *et al.* 2003).

68

69 While in the Chaco region there are historical records of fires produced by indigenous
70 communities as a hunting and/or defence technique (Morello & Saravia Toledo 1959; Morello
71 1983) as well as of natural fires induced by lightning, there is no experimental evidence of
72 recurring fire having been a strong natural selection pressure over evolutionary time, indicating
73 that fire history in the region has presumably not been as long or intense as that of the
74 Mediterranean systems.

75

76 Several studies show that resprouting, which is a widespread trait both in fire-prone and
77 non-fire-prone ecosystems (Wells 1969; Bellingham *et al.* 1994; Lloret *et al.* 1999; Pausas &
78 Verdú 2005), is the main post-fire regeneration strategy of dominant Chaco species, with some
79 species showing a high resprouting capacity following low to medium intensity fires (e.g.
80 Gurvich *et al.* 2005; Bravo *et al.* 2014; Torres *et al.* 2014). Furthermore, studies on germination
81 response of some species conducted in the Chaco region have generally been focused on
82 response to variations in environmental temperature ranging between 5° and 35°C (Funes &
83 Venier 2006; Funes *et al.* 2009; Venier *et al.* 2012). Nevertheless, Jaureguiberry and Díaz (2015)
84 reported that dominant trees, shrubs and herbs of Chaco forest can tolerate (or even be
85 stimulated) by heat treatments of low and medium intensity (70-100°C). However, at high
86 intensity treatments (120-180°C), practically all species exhibited low or no germination.

87

88 Yet, fire recurrence has increased notably in the last decades, mainly due to land use
89 changes and population expansion (Grau *et al.* 2005; Boletta *et al.* 2006; Bravo *et al.* 2010).

90 This phenomenon is especially noticeable in the Chaco Serrano (central Argentina), where fires
91 of different characteristics, ranging from low to medium-high intensity fires depending on
92 environmental conditions and the vegetation physiognomy, occur every year (Bravo *et al.* 2001;
93 Kunst & Bravo 2003; PPMF 2007; Kunst 2011; Argañaraz *et al.* 2015a), challenging the
94 adaptive capacity of plants to regenerate after a fire.

95

96 Herbaceous plants play a key role in fire dynamics, since they provide the fine fuel
97 needed for fire ignition and propagation (Kunst & Bravo 2003). They also have an important
98 ecological role in the post-fire environment, for example in preventing erosion processes by
99 stabilizing the soil (especially in areas with high slope), and in hastening functional restoration
100 by preventing non-native species invasion and in some cases facilitating the establishment of
101 woody species (Keeley *et al.* 1981; Spittler 1995; Maestre *et al.* 2001; Floyd *et al.* 2006; Giorgis
102 *et al.* 2013). However, little is known about the effects of fire on their seeds, with most studies
103 focusing on woody species (Keeley 1987; Hanley & Lamont 2000; Enright & Kintrup 2001;
104 Tieu *et al.* 2001). Particularly in the Chaco Serrano, broad-leaved forbs are an important
105 component of the ecosystem, whereas other herbaceous species such as graminoids are
106 relatively less frequent, especially in areas with mature forest (Giorgis *et al.* 2011).

107

108 While there is considerable evidence showing that herbaceous perennial and annual
109 species differ in several ecological aspects (Pitelka 1977; Garnier 1992; Garnier & Laurent
110 1994; Fenner *et al.* 1999; Corbin & D'antonio 2004; Roumet *et al.* 2006), there is a surprisingly
111 low number of studies on germination response to heat and smoke in those species (e.g. Keeley
112 *et al.* 1981; Keeley *et al.* 1985; Paula & Pausas 2008). Some studies have reported annual
113 species having a high tolerance (or even stimulation) to the mentioned factors, and in some
114 cases they have reported a higher tolerance or stimulation than perennial herbs (Keeley 1991;
115 Keeley & Bond 1997; Paula & Pausas 2008); however none of them compares these strategies
116 explicitly. Still, based on those studies, we can assume that, at least within a given temperature

117 range that does not pose physical limitations to seeds (Bond *et al.* 1999; Hanley *et al.* 2003),
118 annual species in fire-prone ecosystems such as the Chaco region might exhibit a greater
119 tolerance to factors such as heat and smoke than perennial herbs, since they depend solely on
120 the reproductive success of their seeds for survival (Pausas & Keeley 2014).

121

122 The aim of this work was to evaluate the effects of heat shock and smoke experimental
123 treatments on the germination response of annual and perennial herbaceous species that are
124 frequent in the Chaco Serrano of Córdoba province, central Argentina. The experimental
125 treatments will simulate low (70°C) and medium-high (110°C) fire intensities. Considering
126 previous studies on germination response of herbaceous species in other regions of the world
127 and those reported for the Chaco region (Torres *et al.* 2014; Jaureguiberry & Díaz 2015), as well
128 as the above mentioned fire history in the study area, we expect a decrease in the germination
129 capacity of most of the species under the most intense heat treatment and tolerance under the
130 less intense heat treatment. Furthermore, the high variability observed under different smoke
131 treatments in species from other regions, along with the lack of previous experiments involving
132 Chaco species, does not allow us to make a more specific prediction for this treatment. We also
133 compare the germination response between annual and perennial species. Based on the
134 mentioned records, we expect that annual species will exhibit higher tolerance to heat and/or
135 smoke treatments than perennial species.

136 The present work will allow improving our understanding of plant dynamics in fire-
137 prone regions and the post-fire colonization strategy of forb species in burned areas of the
138 Chaco Serrano and similar ecosystems. For example, if the studied species show low tolerance
139 to heat and/or smoke, then it is probable that post-fire colonization of spaces occur mainly by
140 seed dispersal from nearby areas, or by basal resprouting in the case of perennial herbs whose
141 resprout tissues have survived fire.

142

143 **Materials and Methods**

144 ***Study area***

145 The study area is located within the Chaco Serrano District (Cabrera 1976). Vegetation
146 is composed mostly of secondary forest communities and substitute shrublands, alternated with
147 grasslands (Cabido *et al.* 2010; Giorgis *et al.* 2011). The families Fabaceae, Asteraceae and
148 Poaceae are the most numerous in the flora of the study area, and Bromeliaceae, Cactaceae and
149 Solanaceae are also well represented. The most representative species include *Lithraea*
150 *molleoides* (Vell.) Engl., *Acacia caven* (Molina) Molina var. *caven*, *Zanthoxylum coco* Gillies ex
151 Hook. f. & Arn. and *Jarava pseudoichu* (Caro) F. Rojas (Zuloaga *et al.* 1994; Zuloaga &
152 Morrone 1996; Zuloaga & Morrone 1999; Giorgis *et al.* 2011).

153 Fires season spans from June through December (i.e. early winter through early
154 summer), with highest occurrence of fires in August-September (PPMF 2007; Argañaraz *et al.*
155 2015a). Fire frequency varies considerably within the study region, mainly depending on
156 climatic variables, human population density and vegetation type (Argañaraz *et al.* 2015b).
157 Overall, effective burnt area in the study region for the period 1999-2011 was approximately
158 25%, with some areas burnt every 3-4 years (especially grassland areas), others every 5-6 years,
159 and others burnt every 10 or more years (Argañaraz *et al.* 2015a).

160

161 ***Species selection and seed collection***

162 The study focused on forb species common in the Chaco Serrano forest. Sampling sites
163 were located between 500 and 1300 m.a.s.l. For species selection, on the basis of Giorgis *et al.*
164 (2011), who reported a total of 383 forb species for the Chaco Serrano, and considering the
165 logistic restrictions and limitations in seed availability in the field during the proposed sampling
166 period (February-April 2015), we collected seeds from 10 forb species (Table 1): five annual
167 and five perennial species. The selected species are highly frequent in the study area (relative
168 frequency ranging between 6.86% and 69.11%; Annex 1 of Giorgis *et al.* 2011), seven of them
169 being in the top 8% most frequent. Annual species included: *Bidens subalternans* DC., *Conyza*
170 *bonariensis* (L.) Cronquist, *Schkuhria pinnata* (Lam.) Kuntze ex Thell., *Tagetes minuta* L. and

171 *Zinnia peruviana* (L.) L. (all five are Asteraceae). Perennial species included: *Borreria*
172 *eryngioides* Cham et. Schltld. (Rubiaceae), *Sida rhombifolia* L. (Malvaceae), *Solidago chilensis*
173 Meyen (Asteraceae), *Taraxacum officinale* G. Weber ex F.H. Wigg. (Asteraceae) and *Verbena*
174 *litoralis* Kunth (Verbenaceae) (following Zuloaga *et al.* 1994; Zuloaga & Morrone 1996;
175 Zuloaga & Morrone 1999; and updates,
176 <http://www.darwin.edu.ar/Proyectos/FloraArgentina/fa.htm>).

177 The germination period of the selected species is concentrated between the end of
178 winter and spring; the vegetative phase (including sprouting of perennial species) occurs during
179 the spring and summer; and the flowering and fructification occurs in summer and early fall
180 (Atlas de malezas INTA;
181 <http://rian.inta.gov.ar/atlasmalezas/atlasmalezasportal/DetalleMaleza.aspx?pagante=CXF&idmaleza=23585>).

183 Seeds were collected from areas of mature forest, shrubland areas and areas with low
184 and open vegetation. A total of 12 sites were visited for seed collection, located in several points
185 along the Sierras Chicas range, Córdoba province, approximately between 30°58'00''S and
186 31°29'00''S. For each species, seeds of at least 20 healthy-looking (i.e. no evidence of physical
187 damage), sexually mature, randomly selected individuals located at different sites of the
188 sampling area were collected. Seeds were stored in paper bags in a refrigerator for three weeks
189 to 3 months (depending on the species and the collection sites) until the experiments to prevent
190 predation by insects and fungi. Before the experiment samples were mixed to prevent bias from
191 seed collection location. Most of the seed mass data reported in Table 1 were obtained from
192 previous works conducted in the study area and are part of TRY global database (Kattge *et al.*
193 2011). Seed mass of *B. eryngioides*, *S. rhombifolia* and *V. litoralis* was calculated in the present
194 work, following the method described by Pérez-Harguindeguy *et al.* (2013).

195

196 ***Laboratory experiment***

197 Seeds were subjected to the following treatments: control (no heating); heat shock at
198 70°C for one hour, and heat shock at 110°C for five minutes. Treatments consisted of placing
199 seeds in glass dishes and heating them in a convection oven. The heat shock treatments were
200 applied simultaneously to all seeds, although it is acknowledged that separate applications
201 would have produced a more appropriate replication of these treatments (Morrison & Morris
202 2000).

203

204 Heat treatments were selected to cover a range of conditions that seeds might endure in
205 the soil during a fire or in open sites, considering, on the one hand, the temperatures recorded at
206 the soil level in other studies conducted both in the Chaco region (e.g. Bravo *et al.* 2010;
207 Ledesma *et al.* 2011) and in other semiarid regions (Bóo *et al.* 1996; Bradstock *et al.* 1992);
208 and, on the other hand, the effect of soil insulation even at very low depth (Beadle 1940; Valette
209 *et al.* 1994; Bradstock & Auld 1995). Moreover, the selected temperatures are within the range
210 reported as stimulating for several species in similar studies conducted in other regions (Keeley
211 1987; Hanley *et al.* 2001; Luna *et al.* 2007; Ne'eman *et al.* 2009).

212

213 In addition, two treatments combining both heat shock conditions plus a commercial
214 smoke extract (Montazeri *et al.* 2013) diluted in distilled water at a concentration of 1:30 v/v
215 (Baxter *et al.* 1994; Brown & Staden 1997; Doherty & Cohn 2000) were performed (hereafter
216 referred to as 70°C+S and 110°C + S). The diluted smoke was applied to each pertinent replicate
217 (see below) at the start of incubation. Finally, another treatment including only the diluted
218 smoke extract was performed. Hence, each species was subjected to a total of six treatments.

219

220 Seeds were incubated in Petri dishes lined with filter paper moistened with distilled
221 water. Fifty seeds were placed in each dish, with three dishes (replicates) per treatment per
222 species being used. Before incubation, each dish was treated with a broad-spectrum fungicide
223 (Carbendazim and Benzimidazol) to avoid fungal proliferation. Petri dishes were placed in a

224 germination chamber at 25°C and a 12-hour photoperiod for 40 days (in some species, the
225 experiment was ended after 36 days of incubation because no germination had been recorded for
226 one week). This temperature mimics the average maximum spring temperature in the region
227 (Capitanelli 1979), which is the most common germination season for most of the studied
228 species, and has been used in previous studies as an optimum germination temperature (Cony &
229 Trione 1996; Funes *et al.* 2009; D'agostino *et al.* 2012; Venier *et al.* 2012). The Petri dishes
230 were periodically checked for seed germination, with the germination criterion being seeds with
231 radicle emergence. Germination data were used to calculate germination percentage of each
232 treatment for each species. No viability tests were performed.

233

234 ***Data analyses***

235 Statistical analyses were performed using InfoStat software version 2017 (Di Rienzo *et*
236 *al.* 2017, Grupo InfoStat, Facultad de Ciencias Agropecuarias, Universidad Nacional de
237 Córdoba, Argentina). Differences in germination percentages among species and among
238 treatments within species were determined using a Generalized Linear Model (Bates *et al.* 2014;
239 Di Rienzo *et al.* 2017), which included the experimental treatments (i.e. smoke and heat),
240 species and their interactions as fixed factors, assuming a binomial error distribution. The
241 obtained means were then compared using the DGC *a posteriori* test (Di Rienzo, Guzmán,
242 Casanoves pair-wise comparison procedure; Di Rienzo *et al.* 2002). Model selection was based
243 on the Akaike criterion (1972). Model fit was performed via InfoStat, which uses the *lme4*
244 library (Bates *et al.* 2014) in R (R Development Core Team 2008).

245

246 **Results**

247 ***General patterns***

248 Nine of the ten species showed a significant increase in germination with relation to
249 control (i.e. no heat and no smoke) under at least one of the treatments; being *T. officinale* the
250 only species that did not follow this pattern (Fig. 1). The model showed a high influence of

251 'species' in explaining the patterns observed under the experimental treatments ($p < 0.0001$;
252 deviance=2377.89; Table 2); and there was a significant but relatively weak interaction
253 between heat shock, smoke and species ($p < 0.0001$; deviance = 165.36; Table 2). The strength
254 and nature of the interaction varied greatly depending on the species (Fig. 1; see following
255 sections).

256

257 ***Germination response to the combination of heat shocks and smoke extract***

258 Six species had the highest germination percentages under one of the treatments
259 combining heat shock and smoke (Fig. 1). Four of them (*S. pinnata*, *S. chilensis*, *V. littoralis* and
260 *Z. peruviana*) exhibited significantly higher germination percentage in the combined treatment
261 of 70°C + S (Fig. 1). For *B. subalternans*, the treatment combining 110°C +S showed a
262 significantly higher germination, and for *B. eryngioides*, germination percentage was equally
263 high for both combined treatments (Fig. 1).

264

265 Furthermore, *S. rhombifolia* and *T. minuta* also had the highest germination percentages
266 in the treatment combining 70°C + S, but the values did not differ significantly from the
267 germination response obtained in other treatments within the species (70°C for one hour in *S.*
268 *rhombifolia* and smoke extract in *T. minuta*) (Fig. 1). Finally, *C. bonariensis* and *T. officinale*
269 were the only species that showed decreased germination in response to combined treatments of
270 heat and smoke extract with respect to control (Fig. 1).

271

272 ***Germination response to heat shock (no smoke)***

273 Germination percentages obtained in the control treatments were highly variable. Two
274 species showed a germination percentage below 5% (*S. pinnata* and *S. rhombifolia*), whereas
275 others, such as *T. minuta* and *T. officinale*, exceeded 60% (Appendix S1; Fig. 1).

276

277 Six species did not show significant differences between control and heat shock
278 treatments; four species showed a significantly higher germination than the control under the
279 70°C treatment: *B. eryngioides*, *C. bonariensis*, *S. rhombifolia* and *S. chilensis*. Finally, only *S.*
280 *chilensis* had a significantly higher germination percentage under 110°C, but without significant
281 differences from those under 70°C (Fig. 1).

282

283 ***Germination response to smoke treatment (no heat)***

284 Germination response to the application of a commercial smoke extract was very
285 variable among species. Four species exhibited a significantly higher germination percentage
286 than control and both heat treatments: *B. subalternans*, *B. eryngioides*, *T. minuta* and *Z.*
287 *peruviana* (Fig. 1). Furthermore, five species did not show significant differences from control,
288 and only *T. officinale* showed a lower germination percentage than control under the smoke
289 treatment (Fig. 1).

290

291 ***Germination response of annual vs. perennial forb species***

292 In general, annual species showed a higher mean germination than perennials under the three
293 treatments involving smoke (Fig. 1), and also a higher impact of these treatments (i.e. greater
294 difference with respect to control treatment) than perennial species (Fig. 2; Appendix S2).
295 Germination response was on average higher in perennial species under the control treatment
296 and the two heat shock treatments (Fig. 2; Appendix S2), although differences with respect to
297 control were not as high as those mentioned for annuals above.

298

299 **Discussion**

300 ***Germination response to the combination of heat and smoke extract***

301 The six species that had their highest germination in one of the combined heat and
302 smoke treatments showed a synergistic effect of these factors on germination (i.e. a positive
303 interaction between heat and smoke). Accordingly, previous studies conducted with species

304 from other regions also reported highest germination under this type of treatments (Keith 1997;
305 Morris 2000; Enright & Kintrup 2001; Tieu *et al.* 2001; Thomas *et al.* 2003). On the other hand,
306 the antagonistic patterns such as the one observed in *C. bonariensis* and *T. officinale* (Fig. 1) has
307 also been reported for other species (Tierney 2006), although the mechanism underlying this
308 pattern is not clear. A possible explanation is that heat might produce chemical changes in the
309 compounds present in smoke, which in turn can produce changes in seed incubation conditions,
310 such as pH, which may affect germination (Keeley & Fotheringham 1998). In the case of *T.*
311 *officinale* the two combined heat and smoke treatments showed similar germination levels to
312 that with smoke individually, indicating that smoke, regardless of heat application, is the
313 inhibiting factor for this species.

314

315 ***Germination response to heat shock (no smoke)***

316 All the studied species were capable of tolerating the 110°C treatment (i.e. germination
317 similar to the control treatment); *S. chilensis* even showed a significantly higher germination
318 under this treatment (Fig. 1). Bond *et al.* (1999) suggest that high heat tolerance of small-seeded
319 species (less than 2 mg *sensu* Bond *et al.* 1999), such as most in the present work (with the
320 exception of *Z. peruviana*; Table 1) and of broad-leaved forbs in general, may be because these
321 seeds germinate from shallow soil areas, since seedlings cannot emerge from higher depths.
322 Therefore, small seeds are more exposed than large seeds (more than 10 mg *sensu* Bond *et al.*
323 1999) to factors such as heat generated by fire or the high insolation in certain regions. This
324 situation might act as a selective pressure for developing higher tolerance to heat shock in
325 small-seeded species (Hanley & Lamont 2000; Hanley *et al.* 2003), at least within a given
326 temperature range.

327

328 Furthermore, the fact that germination was stimulated mostly by the less intense heat
329 shock treatment (70°C) suggests that such stimulation is not necessarily an indicator of adaptive
330 response to fire, since similar temperatures can occur due to sun exposure in open sites

331 generated by overgrazing, erosion, or burned soils after a fire (Auld & Bradstock 1996; Keeley
332 & Fotheringham 2000). Moreover, our results show that heat-stimulated species also germinated
333 under the control treatment, indicating that they are not strictly tied to post-fire environments.
334 Therefore, both species that tolerated heat shocks and those that were stimulated have great
335 resistance to heat but do not depend on it to germinate (Ooi *et al.* 2014).

336 Patterns of high to medium germination observed under control treatment (i.e. no heat
337 and no smoke) in *T. officinale*, *T. minuta*, *C. bonariensis* and *S. chilensis* agrees with previous
338 findings (Fenner 1980; Washitani 1984; Correia *et al.* 1999; Ferreira *et al.* 2001). The low
339 germination of some of the species has also been reported elsewhere. One possible cause for this
340 is the presence of some type of seed dormancy. For example, *S. rhombifolia* has been reported
341 to have physical dormancy due to a hard seed coat (Chauhan & Johnson 2008), whereas *S.*
342 *pinnata* has been reported to have physiological dormancy (Fenner 1980). Likewise, *Z.*
343 *peruviana* has been reported as having moderate seed dormancy (Rodríguez-Arévalo *et al.*
344 2016). Therefore, in these species the performed treatments were able to break seed dormancy, at
345 least partially. The lack of germination of the remaining seeds could be due to seeds being non-
346 viable (which was not tested in this study) or to specific germination requirements that were not
347 met in the present study.

348

349 ***Germination response to smoke extract (no heat)***

350 The germination response under the smoke extract treatment was variable; five species
351 did not show significant differences in germination from control, whereas *B. eryngioides*, *B.*
352 *subalternans*, *T. minuta* and *Z. peruviana* increased germination with respect to control and to
353 both heat treatments. These results are in agreement with other studies in which smoke was
354 found to be effective in inducing and/or increasing germination of both annual and perennial
355 herbs (Dixon *et al.* 1995; Jäger *et al.* 1996; Keeley & Bond 1997; Lloyd *et al.* 2000; Enright &
356 Kintrup 2001; Ghebrehiwot *et al.* 2011).

357

358 The decreased germination observed in *T. officinale* under this treatment might be
359 attributed to the potentially inhibitory capacity of smoke extract (Brown & Staden 1997; Jäger
360 *et al.* 1996; Gilmour *et al.* 2000), which occurs at different concentrations depending on the
361 species (Keeley & Fotheringham 1998). This could explain the variability observed in our study
362 under the same extract concentration.

363

364 ***Germination response of annual vs perennial forbs***

365 While on average perennial species exhibited a higher germination percentages than
366 annual species under control and 70°C and 110°C treatments (Fig. 2), annual species had higher
367 average germination percentages under smoke, 70°C + S, and 110°C + S than perennial species,
368 showing an opposite relationship to that observed in control treatments (Fig. 2). Thus, the
369 effects of these treatments were much higher for annual species than for perennial ones. The
370 results obtained under smoke, 70°C + S and 110°C + S agree with previous findings showing
371 that in some ecosystems, annual forbs are more tolerant or more stimulated by heat or smoke
372 (Keeley & Bond 1997; Paula & Pausas 2008), and support our hypothesis postulating that
373 annual species are more tolerant to heat and smoke than perennial species. However, when
374 considering all treatments, the hypothesis and prediction formulated are only partially
375 supported.

376 The high variability observed on species' germination and the high influence of species
377 reported by the model makes it difficult to reach firm conclusions regarding differences between
378 life strategies, at least for the group of species selected for this study. Nevertheless, despite the
379 limited number of species used, which demands precaution in the interpretation of the results
380 and in the extrapolation of the results, we believe that our study provides novel and valuable
381 information to better understand the post-fire dynamics of forb species with different life
382 strategies.

383

384 ***Ecological implications***

385 Our results suggest that the studied species are capable of tolerating temperatures
386 associated with low and medium intensity fires, and that smoke (both acting alone or in
387 combination with heat shock) is an effective promoter of germination for most of the species,
388 therefore favouring their performance in post-fire environments, allowing them to colonize the
389 free spaces generated by fire (Keeley & Fotheringham 2000; Hanley & Lamont 2000; Hanley *et*
390 *al.* 2001). Additionally, under increasing fire frequency scenarios herbaceous species could be
391 favoured with respect to woody species, since these latter require longer times between fires to
392 regenerate and be able to colonize post-fire spaces, either through resprouting or recruitment of
393 new individuals from seeds (Silvertown *et al.* 1993; Moles *et al.* 2004). Under such scenarios, it
394 could be expected that the herbaceous species studied here, and others common in the study
395 region, will become more frequent and produce changes in vegetation structure (e.g. species
396 diversity and/or composition, physiognomy) (Verzino *et al.* 2005; Casillo *et al.* 2012; Giorgis *et*
397 *al.* 2013), a process that has already been reported for other fire-prone semi-arid regions (Pausas
398 & Keeley 2009; Keeley & Brennan 2012).

399

400 On the other hand, the prevalence of the annual and/or perennial strategies will depend
401 on factors such as relative abundance in the ecosystem, dispersal ability, relative growth rate,
402 and seed size and production (Garnier 1992; Leishman *et al.* 1995; Moles *et al.* 2004). This
403 could be highly relevant for invasion processes, especially by annual exotic species, many of
404 which are known to outcompete native perennial species under disturbance scenarios (Seabloom
405 *et al.* 2003; Corbin & D'Antonio 2004).

406

407

408 **Conclusions**

409 Germination of all of the studied species was stimulated by at least one of the
410 experimental treatments performed. Eight species responded positively to the combined heat
411 and smoke treatments, four of which showed a synergistic effect on germination. This positive

412 response was mostly under the 70°C temperature, suggesting that the studied species might have
413 an advantage in colonization of environments after low-to-medium intensity fires. Unlike
414 expected, germination response did not decrease under the most intense heat treatment (i.e.
415 110°C).

416 The prediction of germination response in annual vs. perennial species was partially
417 supported, since although on average germination was higher in annual species in all treatments
418 involving smoke, perennial species had higher average germination under the control treatment
419 (i.e. no heat and no smoke) and the two heat treatments alone.

420

421 **Acknowledgements**

422 We thank M.R. Cabido for his assistance on the selection and identification of plants, F.
423 Casanoves and L. Gorné for statistical advice, and G. Funes and M. Giorgis for helpful
424 comments and suggestions during the study. P. Jaureguiberry is an Assistant Researcher for
425 CONICET.

Table 1. List of studied species, indicating botanical family, life history strategy and seed mass. Nomenclature follows Zuloaga et al. (1994), Zuloaga and Morrone (1996, 1999) and updates (following <http://www.darwin.edu.ar/Proyectos/FloraArgentina/fa.htm>). References on seed mass: ^aKattge, J. et al. (2011); ^bthis study.

| Species | Family | Life history strategy | Seed mass (mg) |
|--|-------------|----------------------------|-------------------|
| <i>Bidens subalternans</i> DC. | Asteraceae | Annual forb | 1.6 ^a |
| <i>Conyza bonariensis</i> (L.) Cronquist. | Asteraceae | Annual forb | 1.1 ^a |
| <i>Schkuhria pinnata</i> (Lam.) Kuntze ex Thell. | Asteraceae | Annual forb | 1.0 ^a |
| <i>Tagetes minuta</i> L. | Asteraceae | Annual forb | 0.78 ^a |
| <i>Zinnia peruviana</i> (L.) L. | Asteraceae | Annual forb | 4.86 ^a |
| <i>Borreria eryngioides</i> Cham et. Schlttdl. | Rubiaceae | Perennial forb or subshrub | 0.28 ^b |
| <i>Sida rhombifolia</i> L. | Malvaceae | Perennial forb or subshrub | 1.99 ^b |
| <i>Solidago chilensis</i> Meyen | Asteraceae | Perennial forb | 0.13 ^a |
| <i>Taraxacum officinale</i> G. Weber ex F.H. Wigg. | Asteraceae | Perennial forb | 0.55 ^a |
| <i>Verbena litoralis</i> Kunth | Verbenaceae | Perennial forb | 0.23 ^b |

Table 2. Sequential hypothesis testing for fixed effects (i.e. smoke, temperature, species and their interactions) of the generalised linear model used in the present study. “P” values (last column) lower than 0.05 indicate a significant effect of the corresponding factor.

| | Df | Deviance | Resid. Df | Resid. Dev | Pr(>Chi) |
|---------------------------|----|----------|-----------|------------|----------|
| NULL | | | 179 | 3896.76 | |
| Smoke | 1 | 169.83 | 178 | 3726.94 | <0.0001 |
| Temperature | 2 | 35.81 | 176 | 3691.12 | <0.0001 |
| Species | 9 | 2377.89 | 167 | 1313.23 | <0.0001 |
| Smoke:Temperature | 2 | 8.00 | 165 | 1305.23 | 0.0183 |
| Smoke:Species | 9 | 757.72 | 156 | 547.51 | <0.0001 |
| Temperature:Species | 18 | 104.94 | 138 | 442.58 | <0.0001 |
| Smoke:Temperature:Species | 18 | 165.36 | 120 | 277.219 | <0.0001 |
